Summary. Hypothetical binodal zeolitic structures (structures containing two kinds of tetrahedral sites) were systematically enumerated using tiling theory and characterised by computational chemistry methods. Each of the 109 refineable topologies based on "simple tilings" was converted into a silica polymorph, and its energy minimised using the GULP program with the Sanders-Catlow silica potential. Optimised structural parameters, framework energies relative to $\alpha$-quartz and volumes accessible to sorption have been calculated. 11 of the 30 known binodal topologies listed in the Atlas of Zeolite Framework Types were found, leaving 98 unknown topologies. The chemical feasibility of each structure as a zeolite was evaluated by means of a feasibility factor derived from the correlation between lattice energy and framework density. Structures are described using a model-building approach, and are divided into 15 families, based on common structural features. Many "feasible" structures contain only small pores. Several very open structures were also enumerated, although they contain 3-membered rings which are thermodynamically disfavoured and not found in conventional zeolites.

[^0]We believe that such topologies may be realizeable as framework materials, but with different elemental compositions to those normally associated with zeolites.

Key words: tiling theory, enumeration, zeolites, hypothetical structures

## Introduction

Zeolites find many important applications in science and technology in areas as diverse as catalysis, chemical separation, water softening, agriculture, refrigeration and opto-electronics. 152 distinct structural types of zeolites have now been identified (Baerlocher, et al. 2001). Unusually, the definition of a zeolite is based not on chemical composition or function, but rather on atomic-scale geometry. In order to qualify as a zeolite or zeolite-type material (zeotype), a mineral or synthetic material must possess a framework composed of corner-sharing tetrahedra. There is an additional requirement of "openness", simultaneously dependent on density and smallest ring size, thus excluding denser minerals. Another way of expressing this is in terms of a 4 -connected net in which each vertex, in chemical terms the central atom of a tetrahedron, is connected to its four closest neighbours, normally via an oxygen bridge.

The enumeration of hypothetical zeolitic framework structures (Klinowski 1998) is of considerable scientific and practical interest in terms of generating new nanoporous architectures. Enumeration originates with the work of Wells (Wells 1977; 1979; 1984) on three-dimensional nets and polyhedra. Smith and collaborators (Smith 1988; 1993), Alberti (Alberti 1979), Sato (Sato 1984; 1987), Sherman and Bennett (Sherman \& Bennett 1973), Barrer and Villiger (Barrer \& Villiger 1969), O'Keeffe and collaborators (Boisen, et al. 1999; O'Keeffe \& Hyde 1996b; O'Keeffe \& Hyde 1996a) and Akporiaye and Price (Akporiaye \& Price 1989) found many possible new structures by combining various structural subunits. More recent work involves computer search algorithms (Boisen, et al. 1999; Foster \& Treacy 2004; Mellot-Draznieks, et al. 2000; Treacy, et al. 1997).

Our work is based on advances in combinatorial tiling theory (Dress, et al. 1993). A tiling is a periodic subdivision of three-dimensional space into connected regions, which we call tiles. If two tiles meet along a surface, the surface is called a face. If three or more faces meet along a curve, we call the curve an edge. If at least three edges meet at a point, we call that point a vertex. A network is thus formed by the vertices and edges. The configuration of edges, faces and tiles around a given vertex can be
described via the so-called vertex figure, obtained by placing the centre of a small notational sphere at the vertex and considering the tiling of that sphere formed by the intersections with the different tiles touching that vertex. We have already enumerated all possible Euclidean uni-, bi- and trinodal tilings based on simple vertex figures and all uninodal tilings with vertex figures containing up to six extra edges (Delgado Friedrichs 2001), and the computer program used for this task is available from the authors upon request (delgado@informatik.uni-tuebingen.de).

The tiling approach identified networks with 1, 2, and 3 kinds of inequivalent vertices, which we call uninodal, binodal and trinodal (Delgado Friedrichs, et al. 1999). We have shown that there are exactly 9, 117 and 926 topological types of 4 -connected uninodal, binodal and trinodal nets, respectively, which are based on "simple" periodic tilings (as explained in ref. (Delgado Friedrichs, et al. 1999)). In addition, there are at least 157 additional uninodal nets derived from "quasi-simple" tilings (the vertex figures of which are derived from tetrahedra, but contain double edges) (Delgado Friedrichs, et al. 1999) and which have already been discussed elsewhere (Foster, et al. 2001; Foster, et al. 2003; Foster, et al. 2004a; Foster, et al. 2004b; Simperler, et al. 2004). For example, zeolitic structure types SOD, LTA, RHO, FAU, KFI and CHA are all based on quasi-simple tilings. An example of a non-simple tiling is that of GIS, where the tile has some two-connected vertices.

Here we focus our attention on the binodal structures, i.e., those with two topologically inequivalent types of tetrahedral vertex (T-atom sites) derived only from simple tilings, meaning that they can be readily described by the packing of convex polyhedra, the vertices of which are all three-connected. Structures containing cages are thus found in abundance, while those with, for instance, more "cylindrical" channels are less common, and tend to have lower framework density than the "quasi-simple" structures, with a greater proportion lying in the range of density where most known zeolites are found, as opposed to denser minerals. On the other hand, many of the known zeolite structure types cannot be constructed from simple tilings. Thus, simple tilings cannot therefore generate the complete set of binodal zeolites. Seven of the 21 known uninodal zeolites correspond to simple tilings, and the remaining 14, together with several mineral structures (although not quartz) are constructed using quasisimple tilings. We have found 11 of the 30 known binodal zeolite types, and the remaining 19 will be found by considering quasi-simple tilings, just as with the uninodal structures. The number of potential binodal networks thus generated will be enormous, and their enumeration will require the use of a state-of-the-art
computational facilities. However, only very few binodal structures have previously been enumerated, while nearly all uninodal structures derived from the tilings were previously known, either as crystal structures, or as hypothetical nets. It is therefore of interest to describe the binodal structures derived from simple tilings only.

To characterise the structures, we follow procedures to identical those used in our previous work (Foster, et al. 2003; Foster, et al. 2004b). This involves generating model $\mathrm{SiO}_{2}$ polymorphs from the tiling nets, and optimising them using lattice energy minimisation. Apart from obtaining an optimised structure for each topology, we also calculate a lattice energy, which provides an accurate guide to the thermodynamic stability that such a phase might have. A "feasibility factor", $\vartheta$, derived from the correlation between lattice energy and density calculated for known zeolite structure types, serves as a further measure of thermodynamic feasibility. We have also calculated the accessible volume for each pore system using a standard definition (Cerius ${ }^{2}$ 1999).

In describing the structural characteristics of each framework, we have resorted to the "model building" approach (Baerlocher, et al. 2001; Liebau, et al. 1986; Meier 1986; Smith 1988), which is consistent with descriptions found in the online zeolite database, and allows structures to be classified into "families" if they share certain structural motifs. As part of this analysis we define as a composite building unit (CBU) every small finite unit from which a structure may be generated. These can be corner-, edge-, or face-sharing, or joined to one another by single linkages. The automated assembly of such units is also a potential method of structural enumeration, as demonstrated by Mellot-Draznieks et al. (Mellot-Draznieks, et al. 2002; Mellot-Draznieks, et al. 2000). Zeolite structures may also be described in terms of the strictly defined secondary building units (SBUs), one type of which may be used to build a unit cell of the zeolite, without any sharing of T-atoms. Here, we have not used the SBU approach, finding it more informative to use alternative descriptions (in general our building units tend to be larger). However the SBUs involved may be readily identified, as may the infinite periodic building units (PerBUs). We note that none of the units discussed are intended to represent the precursors from which zeolite crystals grow; neither do they necessarily correspond to the tiles of the original nets.

We discuss the structures in terms of the component units, and relate these to the calculated stability and feasibility. Taken together, thermodynamic feasibilty and the nature of the building units can provide a good initial guide as to which of these structures could be most readily synthesised.

## Energy minimisation

The systematically enumerated nets (Delgado Friedrichs, et al. 1999) were first converted into atomistic models. This was done by inserting a Si atom at each vertex point in the network, and placing a bridging oxygen between each pair of adjacent Si atoms. Each net was scaled such that the vertices were separated by about $3.1 \AA$, a typical Si-Si distance. The resulting structure was then pre-optimised using the DLS (distance least squares) method (Meier \& Villiger 1969) which performs geometric refinement of the structure by fitting bond lengths and angles to the prescribed values, and reduces the amount of computer time needed for the subsequent minimisation of lattice energy. Its use was found to have no influence on the final result: using lattice energy minimisation from the outset gives the same structure, but at greater computational expense. The lattice energy and crystallographic data are those extracted from the GULP minimisations, whereas coordination sequences, bond distances and angles were calculated with zeoTsites (version 1.2) (Sastre \& Gale 2001). The connectivity was additionally checked with software tool KRIBER (version 1.1) (Bialek 1995). Additional calculations were carried out using Cerius ${ }^{2}$ (Cerius ${ }^{2}$ 1999). Structural figures were prepared using GDIS (GDIS 2004) and POV-Ray (POV-Ray 2004). The lattice energy, $\Delta \mathrm{E}_{\text {quartz }}$ given in Table 1, is relative to that of $\alpha$-quartz, calculated using the same potential model, and is thus analogous to the heat of transition reported for several high-silica zeolites (Henson, et al. 1994; Hu, et al. 1995; Moloy, et al. 2002; Navrotsky, et al. 1995; Petrovic, et al. 1993; Piccione, et al. 2000; Piccione, et al. 2001; Piccione, et al. 2002).

## The Feasibility Factor

The well-established relationship between framework density and calculated lattice energy (Foster, et al. 2001; Foster, et al. 2003; Foster, et al. 2004a; Foster, et al. 2004b; Simperler, et al. 2004) was confirmed experimentally (Henson, et al. 1994) for known zeolites. Using the standard least-squares technique, a straight line was fitted to 145 data points obtained from minimising quartz and all the known zeolite topologies in an purely siliceous form (Figure 1). We excluded the four non-silicate structure types which substantially deviate from the rest: WEI (calcium beryllophosphate), CZP (sodium zincophosphate), OSO (potassium berylosilicate) and RWY (gallium germanium sulphide). The line of best fit has the formula $y=-1.4433 x+40.3904$, where $x$ is framework density $\left(\mathrm{F}_{\mathrm{D}}\right)$ and $y$ is $\Delta \mathrm{E}_{\text {quartz }}$. The feasibility factor, $\boldsymbol{\vartheta}$, is then simply the
dimensionless deviation of a data point $\left(x_{1}, y_{1}\right)$ from the line of best fit, given by the vertical offset $\vartheta=\frac{\left|1.4433 x_{1}+y_{1}+40.3904\right|}{1.4433}$. Being formally independent of the framework density, the feasibility factor $\vartheta$ is thus a convenient way of discriminating between candidate structures, and can be compared with the values obtained from known zeolite structures. We minimised all the known zeolite topologies as silica polymorphs, regardless of the actual composition in which they occur, and we believe that $\vartheta$ is a better gauge of the feasibility of the structure than $\Delta \mathrm{E}_{\text {quartz }}$ alone, as evidenced by the fact that seven of the ten lowest $\vartheta$ values in Table 1 belong to structures with known zeolite topologies. A ranking in order of ascending $\Delta \mathrm{E}_{\text {quartz }}$ would, in contrast, produce only four. Virtually all of the topologies which are known in the form of silicates, aluminosilicates or aluminophosphates, including those with low levels of heteroatom substitution, have $\vartheta<5$. This reflects the similarity of preferred geometry between (alumino)silicates and AlPOs. The highest values of $\vartheta$ are 5.03 for AFY (Co-AlPO-50), which has $19 \%$ framework cobalt, and 5.18 for AHT, only known as the thermally unstable material AlPO-H2. By analogy, we define structures with $\vartheta<5$ as feasible "conventional" zeolites, i.e., those for which natural zeolites along with highsilica and AlPO forms are known. Framework types with more "exotic" compositions have $\vartheta>5$. For example, the zincosilicates VNI, VSV and RSN have $\vartheta$ of 5.75, 6.07 and 6.09 , respectively. Beryllosilicates, generally containing 3-rings, also have higher $\vartheta$, e.g. LOV (6.51), NAB (10.99) and OSO (23.30), while the beryllophosphate weinebeneite has $\vartheta=12.24$ and the zincophosphate CZP $\vartheta=20.92$. We therefore propose that $\vartheta$ values up to 25 indicate that the topology may be feasible in the form of an "oxide" material. Above this, we note that for RWY, the only zeotype structure known solely as a framework sulphide, $\vartheta=51.69$. Many other compositions, such as metal-organic frameworks, are of course, possible. This means that although a structure may be deemed highly unfeasible as a zeolite, it may exist in other chemical forms. Also, the precise value of $\vartheta$ will be an unreliable guide in the high region, since it is based only on a silica model. In order to gauge the feasibility of a particular topology in a different composition, it would be necessary to carry out separate series of computations, taking into account the actual composition.

The Cerius ${ }^{2}$ software suite (Cerius ${ }^{2}$ 1999) was used for visualising and manipulating the structures and for calculating free volumes, space group symmetry and other parameters. In addition to calculating the energetics of the hypothetical structures, it is important to compare the calculated values with the values for all
known zeolite frameworks. Thus all relevant properties were also calculated for the purely siliceous forms of all known zeolite topologies. Lattice energies were calculated relative to $\alpha$-quartz, the most stable form of the mineral at ambient temperature.

The "available volume", defined as the difference between the volume of the unit cell and the effective volume of all the atoms, depends on the van der Waals radii used for each atom. "Occupiable volume" is the volume which can be occupied by a probe molecule with a given radius as it probes the surface of the structure. The "accessible volume" is determined by tracing out the volume by the centre of the probe molecule as it follows the structure contours, but with the extra requirement that the probe must enter the unit cell from the outside via sufficiently wide pores or channels. The accessible volume gives an indication of the space available within each structure for applications in molecular sieving and catalysis. The calculations of the accessible volume were performed using the Free Volume module of the Cerius ${ }^{2}$ package, which applies the Connolly method (Connolly 1985). consisting of "rolling" a probe molecule with a given radius over the van der Waals surface of the framework atoms. We have used a probe molecule with a radius of $1.4 \AA$ (such as water) and 1.32 and $0.9 \AA$ for the radii of O and Si atoms, respectively. The void volume, enclosed within the Connolly surface, was calculated first. The accessible volume was then calculated by requiring the probe molecule to enter the unit cell from the outside.

## Results and Discussion

Of the 117 structures, eight could not be optimised, either because refinement was not possible, or because of failure during minimisation, usually resulting in loss of the original network topology. The remaining 109 structures are described below. For the most part, these minimised smoothly without any loss of symmetry, although there are a few whose low-energy symmetry is lower than that of the original space group. In these instances, the original space group is shown in parentheses in Table 2.

Figure 1a-b gives the plot of framework energy relative to $\alpha$-quartz, $\mathrm{E}_{\mathrm{F}}$, versus the framework density, $\mathrm{F}_{\mathrm{D}}$, for all known zeolites. Relative framework energies of the hypothetical binodal frameworks range from $11.15 \mathrm{~kJ} \mathrm{~mol}^{-1}$ (structure 2_114) to as much as $515.43 \mathrm{~kJ} \mathrm{~mol}^{-1}$ (structure 2_72) (Figure 1c). Figure 1d plots the framework energy versus the framework density for the hypothetical binodal structures with energies
below $30 \mathrm{~kJ} \mathrm{~mol}^{-1}$, the range considered as the most "desirable", and with framework densities typical of the known zeolites.

Figure 2a gives the plot of accessible volume versus framework density for the known structural types and Figure 2b-c the corresponding plot for hypothetical binodal zeolites. Low framework density structures are of particular interest, as they have very high accessible free volumes. Of the structures with framework densities below 18 Si atoms $/ 1000 \AA^{3}$, structures 2_57, 2_58, 2_59, 2_82, 2_85, 2_86, 2_87, 2_91, 2_95, 2_96, 2_102, 2_103, 2_106, 2_108, 2_109, 2_110, 2_112, 2_113, 2_114, 2_117 are energetically stable (Figure 1c). Many hypothetical structures have dense frameworks, which are largely inaccessible. However, as many known zeolite topologies have low accessible volumes (Figure 2a), a structure cannot be ruled out as a feasible topology on the basis of the low accessible free volume, even though it may be of no interest to sorption, ion exchange or catalysis. A plot of framework density for known zeolites and for dense silicate frameworks against the size of the smallest ring in the structure (Brunner \& Meier 1989), shows that very open frameworks with low $\mathrm{F}_{\mathrm{D}}$ have the largest number of 4 - and 3-membered rings, and that there is a gap in $F_{D}$ between compact minerals, such as quartz and tridymite, and the zeolite frameworks. The lower boundary of $\mathrm{F}_{\mathrm{D}}$ for known zeolites is from about 11 tetrahedral atoms per $1000 \AA^{3}$ in materials with 4membered rings to about 17 tetrahedral atoms in materials with $5+$ rings, where the plus sign signifies that some tetrahedral atoms are associated only with the larger rings.

Figure 3 plots the framework energy with respect to $\alpha$-quartz for the known zeolitic structures and the hypothetical binodal structures versus the accessible volume, thus combining information contained in Figures 1 and 2. Structures of the greatest practical interest are those with low energies and large volumes (see inset in Figure 3b). Full details of all the structures have been recently published elsewhere (Foster, et al. 2004b). Crystallographic CIF files from which powder X-ray diffraction patterns can be easily calculated are given in Supplementary Information.

The structures have been divided into fifteen families, the members of which share a common building scheme or structural unit. As explained above, the building units used do not necessarily equate to SBUs or PerBUs in the strict sense. We also note that the allocation of a structure to a certain family is not unequivocal: there are several structures which could equally belong to more than one family. The order in which the various families are discussed is dictated by the feasibility factor of the most feasible structure in that family. Members of a particular family are shown in Figures 4-18 in the same order. The more feasible structures will thus be encountered earlier in the
following sections, with the exception of the "orphan family" which contains several chemically feasible members. In describing the various structures, we use standard nomenclature from the zeolite literature. For instance, "D6R" refers to a double six-ring unit. In describing polyhedral cages or units, the $\left[\mathrm{M}^{\times} \mathrm{N}^{y}\right]$ system adopted by Smith (Smith 1988) is also used, where $(M, N)$ is the number of edges defining a given face and $(x, y)$ is the number of times that face appears in the polyhedron. Results are also tabulated in Table 1 (in order of $\vartheta$ ) and Table 2 (in numerical order of the structures). Table 1 gives $\vartheta, \Delta \mathrm{E}_{\text {quartz }}$, the framework density and the coordination sequences of the T sites. Table 2 gives the crystallographic data.

## ABC-6 family

Of the 109 refinable binodal structures, thirteen (2_87, 2_89, 2_84, 2_90, 2_86, 2_83, 2_107, 2_110, 2_106, 2_108, 2_78, 2_40 and 2_33), can be described using the building scheme for the ABC-6 family (van Koningsveld 2004). Six of these are known frameworks: $2 \_89=$ ERI, 2_84 = EAB, 2_90 = SAT, 2_83 = LEV, 2_107 = LOS and 2_78 = AFX. The PerBU of the family consists of a hexagonal array of isolated 6-membered rings, which are related by pure translations along (100) and (010). A three letter code (A, B, and C) gives the connection mode of the layers along (001). The 6-membered rings of $A$ are centred at ( 0,0 ), while layer $B$ is shifted by $(+2 / 3 a,+1 / 3 b)$ and layer $C$ by $(+1 / 3 a,+2 / 3 b)$. Connection between 6 -rings in adjacent layers is invariably via 4 -rings. In (001) projection, there is a close similarity between all the structures of this family, epitomized by that of 2_106 (Figure 4a), where the hexagonal array of 6-rings, interspersed by 4-rings, is clearly evident. Each structure is uniquely characterised by its (001) stacking sequence, and these sequences are also illustrated in Figure 4 in projections of the unit cells perpendicular to (001). The stacking sequences of the 13 structures (in order of their "thermodynamic feasibility") are $\operatorname{ABBACBBC}(\mathrm{A})$ for 2_87 (Figure 4b), ACAABA(A) for 2_89 (ERI) (Figure 4d), ACCABB(A) for 2_84 (EAB) (Figure 4 e ), $\mathrm{AABABBCBCCAC}(\mathrm{A})$ for 2_90 (SAT) (Figure 4f), $\operatorname{ABBC}(\mathrm{A})$ for $2 \_86$ (Figure 4 g ), AACBBACCB(A) for 2_83 (LEV) (Figure 4i), $\operatorname{ABAC}(A)$ for 2_107 (LOS) (Figure 4j), $\operatorname{ACABABCBC}(A)$ for 2_110 (Figure 4k), $\operatorname{ACABCB}(A)$ for 2_106 (Figure 41), ACACBABACBCB(A) for 2_108 (Figure 4m), $\operatorname{ACCAABBA(A)~for~2\_ 78~(AFX)~(Figure~}$ 4 n ), $\operatorname{ACCCBBBAA}(\mathrm{A})$ for 2_40 (Figure 4o), and $\operatorname{AAAACCCCBBBB(A)~for~2\_ 33~(Figure~}$ 4q). 2_87, 2_89, 2_84, 2_107, 2_106 and 2_78, have hexagonal symmetry, space group $P 6_{3} / \mathrm{mmc}$, while 2_90, 2_83, 2_110, 2_108, 2_40 and 2_33 (all $R-3 \mathrm{~m}$ ) and 2_86 ( $P-3 \mathrm{~m} 1$ ) are trigonal. The ABC-6 structures, both known and hypothetical, are among the most
thermodynamically favoured as silica polymorphs and, as can be seen from Table 1, have high chemical feasibilities $(0.08<\vartheta<0.98)$ except for 2_40 and 2_33, which have $\vartheta$ of 14.97 and 20.83, respectively. In terms of their pore structures, 2_110, 2_106 and 2_108 have cages only accessible through 6-rings. In contrast, 2_87, 2_86 and 2_78 possess 8 -rings as the maximum pore. The ABC-6 structures may also be thought of in terms of stacks, or chains, of cages linked parallel to the (001) direction though 6-rings and, depending on symmetry, there are either one or two distinct types of stack. For example, the most feasible structure $2 \_87$ contains both the $\left[4^{9} 6^{2} 8^{3}\right]$ gmelinite cages, and [ $4^{9} 6^{8} 8^{3}$ ] EAB cages. In contrast to the case of EAB, where these cages are in different (001) stacks, in 2_87 they alternate along (001) (Figure 4c). Parallel to these are stacks of alternating sodalite cages and double 6-rings (D6R). 2_83 also has the alternating chains of D6R and sodalite cages, but parallel to these are stacks only containing LEV cages (Figure 4h). The less dense structures 2_40 and 2_33 are interesting, as they have large cages linked through elongated 10 and 12-rings, respectively (Figure 4 p and 4 r ). However, these structures are less stable, containing stacks of two and three D6R, respectively, linked though shared 6 -rings.

## [ $3^{2} 5^{6}$ ] family

Four structures (2_103, 2_55, 2_56 and 2_104) are built up from columns of $\left[3^{2} 5^{6}\right]$ polyhedral units (Figure 5b) arranged hexagonally so as to give 12-membered ring channels along the $c$ direction (Figure 5a). In the most stable framework, 2_103 (Figure $5 \mathrm{a}-\mathrm{c}$ ), the $\left[3^{2} 5^{6}\right]$ units are linked by sharing their "terminal" 3-membered ring windows (Figure 5c), with each alternate unit related to its neighbour by a $180^{\circ}$ reflection. Structure 2_55 has these small cage units separated by a $\left[3^{2} 4^{3}\right]$ unit (i.e., a trigonal prism, or D3R) (Figure 5d), with the large channels cross-linked via elongated 8-rings. 2_56 and 2_104 (Figure 5e-f) are distorted counterparts of 2_55 and 2_103, respectively. In these trigonal structures, the distortion of the building units arises from the lack of alternation along $z$, entailing a "twist" of the units in order to ensure that the 3-rings remain eclipsed. The distortion is slightly smaller in 2_56 due to the interposition of the D3R units. None of these four are known structures, though 2_103 is expected to be highly chemically feasible $(\vartheta=0.30)$ as, to a lesser extent, is $2 \_55(\vartheta=7.61)$. By contrast, the $\vartheta$ values for 2_56 and 2_104 are 38.29 and 64.22, respectively.

We also define three more members of this family, 2_112, 2_102 and 2_80 (Figure $5 f, h$ and $j$ ), which contain the mentioned $\left[3^{2} 5^{6}\right]$ unit (Figure 5b), though with different building patterns. For example, in $2 \_112$ the $\left[3^{25} 5^{6}\right]$ units are linked via single oxygen
bridges (Figure 5h). As with all the structures belonging to this family, the two topologically distinct types of T-site are the 3-ring site (T1) and the "equatorial" site (T2). In 2_112, each unit is linked to twelve neighbours, with a T1 site of one unit always linked to a T2 site in a neighbouring unit (and vice versa). In this way, the larger cage (Figure 5i) is also formed and having 6 -rings as its maximum aperture. A projection of the cubic unit cell is given in Figure 5g. In 2_102 (Figure 5j) the units are linked via double T1-T2 linkages, defining 4-rings (Figure 5k). This hexagonal structure is less dense than 2_112, with its pore system being accessible via 8-membered ring windows. In structure $2 \_80$ (Figure 51 ), the $\left[3^{2} 5^{6}\right]$ units are linked to one another by double T1-T1 and T2-T2 linkages (Figure 5m), defining large cages (Figure 5n) accessible through 8-ring channels running in all three directions. Both 2_112 and 2_102 are highly feasible, with $\vartheta=4.66$ and 6.08 , respectively, as opposed to $2 \_80$ which has $\vartheta$ $=87.12$. For the latter structure, the topology imposes a degree of distortion on the [ $3^{25} 5^{6}$ ] polyhedra as can be seen in some of the concave $\mathrm{T}-\mathrm{O}-\mathrm{T}$ angles.

## AWW family

There are nine structures which we describe as members of the "AWW family" since they share a small $\left[4^{6} 6^{4}\right]$ cage as the common building unit the (Figure 6a). Six of these structures, 2_88 (which has the actual AWW topology), 2_85, 2_59, 2_58, 2_100 and 2_63 are tetragonal, with columns of larger cages parallel to (001), having 8-ring windows as the maximum pore diameter in that direction. The archetypal example is the AWW $\left[4^{8} 6^{8} 8^{2}\right]$ cage (Figure 6b) which stacks through shared 8-rings (Figure 6e). Figure 6c shows the (001) projection of 2_85 which is typical of this series.

Depending on the linkage pattern of the $\left[4^{6} 6^{4}\right]$ building units along (001), different types of large cage are defined. In AWW, the $\left[4^{6} 6^{4}\right]$ units are connected "end-on", through shared 4-rings (Figure 6d). In 2_85, they alternate in orientation along the chain, with the shared 4-rings found on a mirror plane (Figure 6f). Two alternating types of larger cage are thus defined, $\left[4^{8} 6^{12} 8^{2}\right]$ and $\left[4^{8} 6^{4} 8^{2}\right]$ (also found in the known structures SAS and ATN respectively; Figure 6g). 2_59 has the $\left[4^{6} 6^{4}\right]$ units interspersed by D4R (Figure 6h), giving rise to larger $\left[4^{12} 6^{4} 8^{6}\right]$ (SAV) cages (Figure 6i). 2_58 also has two type of alternating cages, $\left[4^{12} 6^{8} 8^{6}\right]$ ("elongated alpha cage") and $\left[4^{12} 8^{6}\right]$ (Figure 6 k ), while 2_100 and 2_63 (Figure 61-o) have only one type of 8-ring channel cage, denoted as $\left[4^{4} 5^{8} 6^{4} 8^{2}\right]$ and $\left[4^{8} 6^{12} 8^{2}\right]$, respectively. The first four structures (AWW, 2_58, 2_59 and 2 _85) fall within the feasible range, with $\vartheta=0.32$ to 6.04 , while $2 \_100(\vartheta=22.42)$ and
$2 \_63(\vartheta=73.83)$ are less feasible. In the latter structure this is evidenced by the unfavourable T-O-T angles seen in Figure 6n.

There are also three cubic structures which contain the same building unit (2_109, $2 \_97$ and 2_60), with $2 \_109$ being by far the most feasible of the three $(\vartheta=5.67)$. For these three structures, the $\left[4^{6} 6^{4}\right]$ units alternate with sodalite or beta cages in a chain along (100) (Figure 6p). Along (111) there are also chains of cages, with the repeat unit being three sodalite cages and one [ $\left.4^{4} 6^{14}\right]$ cage (Figure 6q). In 2_97, the chains of $\left[4^{6} 6^{4}\right]$ units alternate via a mirror plane (Figure 6r) and are extended in three directions of the structure, with $\left[4^{4} 5^{4}\right]$ units linked by 4 -rings (Figure $6 s$ ) and producing the $\left[5^{12} 6^{20}\right]$ supercages (Figure 6 t ). The maximum aperture in this structure is again a 6 -membered ring window. 2_60 has the $\left[4^{6} 6^{4}\right]$ units linked by D4R (Figure $6 u$ ) such that the chains intersect in three dimensions, thus defining large $\left[4^{6} 6^{24}\right]$ supercages (Figure 6v). 2_97 ( $\vartheta$ $=16.99)$ falls within the extended range of oxide feasibility, whereas 2_60 $(\vartheta=80.04)$ does not.

## Supercage family

Eleven structures contain sodalite or LTA (alpha) cages linked by smaller prismatic units in such as way that it also generates much larger cages. All the structures have cubic or pseudo-cubic symmetry, an example of which can be seen in the (100) view of 2_45 (Figure 7a). Structure 2_74 has the framework of the mineral tschörtnerite (TSC) with both sodalite and alpha cages linked via D6R (Figure 7b), thus defining the large TSC cage (Figure 7c). The order in which the remaining structures are shown in Figure 7 is determined by their chemical feasibility factor, $\vartheta$ although it is convenient to discuss them in a slightly different order.

Structures 2_35 and 2_31 form a series together with the FAU structure, which is composed of sodalite cages linked tetrahedrally via D6R. Structure 2_35 is formed by replacing each single D6R in FAU by stacks of two D6R (Figure 7d). Similarly, 2_31 is generated by the addition of a third D6R to the stacks (Figure 7h). Consequently, the structures contain tetrahedral "super-faujasite" cages, accessible respectively through 18 and 24 -membered rings (Figure 7 e and i). As for FAU, the ideal topological symmetry of the two frameworks is $F \mathrm{~d}-3 \mathrm{~m}$. However, on minimisation, 2_31 exhibits a slight preference for $R-3 \mathrm{~m}$ (i.e., there is a rhombohedral distortion). 2_35 and 2_31 are both feasible as oxide materials, with $\vartheta$ of 10.69 and 13.16, respectively. 2_45 and 2_36 can similarly be imagined as belonging to a series with RHO, a structure formed by alpha cages linked octahedrally via D8R. In fact, the RHO structure is body-centered, since
positioning the alpha cages on the lattice points of a primitive cubic lattice automatically defines a parallel network of alpha cages and D8R based on the bodycentered lattice points. However, considering only the "primitive lattice" of cages, replacement of the D8R by stacks of two and three D8R gives structures 2_45 and 2_36 respectively (Figure 7 f and v). Both have $\mathrm{Pm}-3 \mathrm{~m}$ symmetry and further contain cubic "super-LTA" cages with 12 and 16-membered ring apertures respectively (Figure 7 g and $w)$. Of the two, $2 \_45$ is relatively feasible $(\vartheta=12.91) .2 \_24$ and $2 \_20$ are related to the LTA structure, since they can be generated by linking sodalite cages and D4R. In 2_24, the D4R of the LTA structure are replaced by face-sharing stacks of two D4R (Figure 7 j ), and in $2 \_20$ by stacks of three D4R (Figure 7p). They have the same supercages as 2_45 and 2_36 (Figure 7 k and q), and similar $\vartheta$ of 13.28 and 16.11, respectively. 2_27 and 2_21 can also be considered part of a series with LTA, except in this case it is the alpha cages which are retained and the linkages between them expanded. While in LTA each alpha cage shares 12 D4R with its neighbours, in 2_27 an additional D4R is added to each link (Figure 7n), and 2_21 has stacks of three D4R (Figure 7r). The delineated "expanded sodalite" cages thus possess 9- and 12membered rings, respectively (Figure 7o and s). The final pair, 2_39 and 2_32 form a series derived from KFI, containing alpha cages are connected via shared D6R which are replaced by stacks of two and three D6R in 2_39 and 2_32, respectively (Figure 71 and t). The supercages shown in Figure 7 m and u may be denoted as $\left[4^{20} 8^{2} 12^{4}\right]$ and [ $4^{28} 8^{2} 16^{4}$ ], respectively, with both topologies ideally having Im-3m symmetry, as does KFI. Although in our modelling the 2_39 structure minimises into P1, it is the more feasible of the two with $\vartheta=13.86$.

## SAS family

These structures are analogous to the AWW family as they contain stacks of large cages linked unidirectionally by 8 -rings. Figure 8 a shows the ( 001 ) projection of structure 2_54 which is typical of all four tetragonal structures belonging to this family and having $I 4 / \mathrm{mmm}$ space group symmetry (2_54, 2_57, 2_81(SAS) and 2_95). The basic building units may be thought of as smaller polyhedra arranged in parallel chains. In the case of 2_81, which has the SAS (STA-6) topology, the basic units are D6R hexagonal prisms, which form a chain by sharing 4-rings alternating in orientation ( $90^{\circ}$ rotation) about $z$ (Figure 8d), thus defining the classic $\left[4^{8} 6^{12} 8^{2}\right]$ SAS cages (Figure 8e). $2 \_95$ is a highly feasible $(\vartheta=0.93)$ structure in which $\left[4^{4} 5^{4}\right]$ units are linked into chains via 4-rings (Figure 8b), with the two types of alternating larger cages (Figure 8c) being
[ $\left.4^{12} 8^{6}\right]$ (also found in $2 \_58$ and 2_62) and $\left[4^{8} 5^{8} 8^{6}\right]$. When compared to SAS, in 2_57 an additional D4R is interposed between the alternating D6R (Figure 8h), thus defining the larger cages (Figure 8i), which link to their neighbours through ten 8-membered ring apertures. 2_54 is built analogously, from chains of alternating D8R and D4R (Figure 8f) forming larger cages (Figure 8g) containing fourteen 8 -membered rings and separated by D8R units. Aside from SAS and 2_95, both 2_54 and 2_57 are also quite feasible as zeolites ( $\vartheta=3.18$ and 5.51 , respectively).

## [ $4^{2} 5^{8}$ ] family

These structures have as a building unit the small $\left[4^{2} 5^{8}\right]$ cage shown in Figure 9b. In four of the structures, these units are linked into chains through the 4-rings which cap the cages, in a very similar manner to the linking of the $\left[3^{2} 5^{6}\right]$ units in that family. These structures are tetragonal with $\left[4^{2} 5^{8}\right]$ chains running along (001), and have large cages accessible through 8 -rings. The projection of 2 _ 91 along (001) is typical of this family (Figure 9a). 2_91 (Figure 7a, c and d) is the most feasible of these structures ( $\vartheta=$ 0.95 ), and has $\left[4^{2} 5^{8}\right]$ cages linked through D4R, with a chain repeat motif of two cages and two D4R, plus a $45^{\circ}$ twist being introduced at each cage. In 2_114, another highly feasible structure with $\vartheta=2.17$ (Figure $9 \mathrm{e}-\mathrm{f}$ ), the cages are directly linked through shared 4 -rings, although each is still rotated by $45^{\circ}$ about (001) with respect to its neighbours. 2_92 (with D4R spacers in the chain, Figure 9g-h) and 2_115 (direct 4-ring sharing, Figure 9i-j) are analogous structures to 2_91 and 2_114, respectively, but with only half the chain repeat distance, entailing considerable distortion of the $\left[4^{2} 5^{8}\right]$ cages so that the 4-rings are translationally equivalent. Both structures are far less feasible, as is a fifth structure, 2_116 (Figure $9 \mathrm{k}-1$ ), in which the $\left[4^{2} 5^{8}\right]$ units are linked into chains via pairs of T-O-T linkages (Figure 91). In the latter, the chains are interconnected so as to run in all three directions of the cubic lattice, and the structure also contains sodalite cages, each of which shares its 4 -ring windows with $\left[4^{2} 5^{8}\right]$ units.

## AST family

Structure 2_101 (Figure 10a-c) is topologically identical to the known zeolite AST (AlPO-16) (Baerlocher \& McCusker 2004; van Koningsveld 2004). The structure contains the characteristic $\left[4^{6} 6^{10}\right]$ cages (Figure 10c) but may also be thought of in terms of D4R units connected through O-T-O bridges (Figure 10b). In this family we have also identified three other structures containing D4R, not directly linked through shared atoms. In 2_73 (Figure 10d-f), the D4R connect through single oxygen bridges and,
apart from containing sodalite cages, the structure also possesses the large tetrahedral cages shown in Figure 10f, which interconnect through 12-ring apertures. 2_61 (Figure $10 \mathrm{~g}-\mathrm{i}$ ) is a tetragonal structure containing the cages shown in Figure 10i, which have oval-shaped 10 -rings as their largest apertures. The D4R connect via a network of 6rings and puckered 4-rings. Topologically, 2_13 (Figure 10j-1) is an elaboration of the AST structure in which those T-atoms which do not form part of D4R are replaced by [3] tetrahedra of T-sites, a structural feature not found in aluminosilicate zeolites, although present, for instance, in the zeotypic sulphide RWY. Whilst bearing this proviso in mind, all three unknown structures can be considered chemically feasible, though not in "traditional" zeolite (or AlPO) compositions, having feasibility factors $\vartheta$ between 13.62 and 26.62. In addition to the $\left[3^{4}\right]$ unit, we note that the D4R is a structural feature shared with known germanate frameworks found in the range "extended" feasibility.

## D8R family

This family is formed by four structures which contain the double 8-ring (D8R) as a structural unit. 2_47 (Figure 11a-c and f) has a cubic structure in which the building unit may be thought of as a D8R with four D4R attached to alternate 4-ring faces (Figure $11 \mathrm{~b}-\mathrm{c}$ ). These units do not link directly to one another but are arranged so as to define the large $\left[4^{24} 6^{8} 8^{18}\right]$ (TSC) cages shown in Figure 11f. The structure also contains stacks of LTA alpha cages, which alternate with smaller cages and are interconnected through 8rings. 2_19 and 2_17 form part of a homologous series of structures, together with the uninodal structure 1_11 (Foster, et al. 2003), one of the nine simple uninodal tilings. The latter structure has a body-centered cubic framework based on chains of D8R and D4R which are linked in all three directions. 2_19 has the same structure, except that the D4R in 1_11 are replaced in 2_19 by pairs of face-sharing D4R (Figure 11d), and in 2_17 by groups of three D4R (Figure 11e). As a result, the large $\left[4^{60} 8^{6} 18^{8}\right]$ and $\left[4^{84} 8^{6} 24^{8}\right]$ cages shown in Figure 11g-h are defined. The more complex 2_34 structure (Figure 11i-k) also possesses the D8R/D4R units, but with the addition of $\left[4^{6} 6^{4}\right]$ AWW cages which link the units together through edge-sharing (Figure 11j), thus forming large cages having 12rings as its maximum aperture (Figure 11k). Topologically, the tile which corresponds to this cage is the largest among this set of binodal frameworks, with 74 faces, 144 vertices and 216 edges. 2_34 shares the space group Im-3m with both 2_19 and 2_17. $2 \_47$ is certainly thermodynamically feasible, with $\vartheta=3.02$, while $2 \_17$ and $2 \_19$ have $\vartheta$
$=13.96$ and 13.39, respectively, despite having extremely low framework densities of 8.17 and $6.05 \mathrm{~T} / 1000 \AA^{3}$, respectively.

## AFY family

Structure 2_50 is topologically identical to the known structural type AFY (AlPO50). The secondary building unit of this family is a D4R, which in AFY form hexagonal layers (Figure 12a) and are "tilted" with respect to the 001 plane. These layers then repeat through simple translation along $c$, most clearly seen in (120) projection (Figure 12c) (Baerlocher \& McCusker 2004; van Koningsveld 2004). If instead, the layers alternate in orientation by means of a mirror plane (i.e., ABA rather than AA) then framework 2_51 is formed (Figure 12b and d). The unit cell is roughly doubled in size along $c$ and hence 2_51 has higher symmetry, $P 6_{3} / \mathrm{mcm}$ compared to $P \overline{3} 1 \mathrm{~m}$ for AFY. Both have low $\vartheta$ values: 5.03 and 5.18 for 2_50 and 2_51, respectively, making 2_51 virtually as feasible as AFY.

## D6R family

This family comprises seven structures (2_6, 2_30, 2_53, 2_75, 2_76, 2_77 and 2_82) which have in common D6R hexagonal prisms as building units, although of these there are only two (2_76 and 2_75) for which D6R (i.e., 6-6) may be strictly defined as a secondary building unit. The structures are all cubic, space group $\mathrm{Pn}-3 \mathrm{~m}$, with the exception of the two structures previously mentioned. The first five members of the group may be thought of in terms of chains running along (110) in which the D6R are linked by various combinations of rings. Each D6R is rotated by $60^{\circ}$ with regard to its chain neighbours, with the chains in turn linking to form sheets along (100). This is clearly seen for 2_82 in Figure 13e, where the adjacent D6R are linked by units of two 4rings and a 6 -ring, with the latter bridging to an adjacent chain. A twisted 6 -ring is thereby defined directly between the D6R. In the most feasible member of the family, 2_53 ( $\vartheta=5.11$ ), the link unit includes D4R, giving rise to the characteristic motif shown in Figure 13b, where four D6R are connected to a single D4R. This structure also contains FAU supercages (Figure 13a) which are linked via the $\left[4^{18} 8^{6} 12^{2}\right]$ cages shown in Figure 13c. In these, the two puckered 12-rings are roughly parallel at an average distance of around $5.0 \AA$. In addition to the structural features already mentioned, 2_82 also possesses distorted $\left[4^{12} 6^{8} 8^{6}\right]$ alpha cages (Figure 13d) whose 8-rings are connected via the $\left[4^{8} 6^{4} 8^{2}\right]$ cages (Figure 13f), which are topologically identical to the cages found in the ATN zeolite structures, although again the shape here is less regular with the
parallel 8-rings being elongated in orthogonal directions. 2_82 is another feasible structure with $\vartheta=9.41$. In 2_77, the D6R chains are linked by units of three 4 -rings (Figure 13h), and the structure has FAU supercages, although much more distorted than in 2_53 (Figure 13g); in particular the 12-rings are puckered and exhibit a triangular distortion, with the $\left[4^{12} 6^{6} 12^{2}\right]$ units linking supercages (Figure 13i) exhibiting -3 symmetry. In 2_30, the spiro-5 unit links the D6R into chains (Figure 13k) and a rather complex pore structure ensues, which is not trivial to describe, but some idea of its shape may be derived from Figure 13j: the largest pore apertures are elongated 12-rings and puckered 18-rings, an example of which is shown in Figure 131. 2_77 and 2_30 are on the boundary of the extended range of feasibility with $\vartheta=24.27$ and 33.21, respectively, with 2_30 containing both 3 and 4-membered rings. 2_6 also contains 3rings linked into [ $3^{4}$ ] tetrahedra which connect the D6R as shown in Figure 13p. A complex pore structure analogous to that of 2_30 is thus generated (not shown) having puckered 24-rings (Figure 13q). Finally, structures $2 \_75$ and $2 \_76$ are the "odd ones out" of the family since it is not possible to describe them using the D6R chain model. 2_75 is very unusual as it contains both "regular" and flattened sodalite cages connected through 6-rings (Figure 13m, where the D6R are also illustrated). An oblate sodalite cage is shown in plan view in Figure 13n, whereas a large cavity, which links through puckered 12-membered ring pores, is shown in Figure 13o. 2_76 contains (differently) distorted beta cages (Figure 13r), as well as larger cages (Figure 13s) accessible through both approximately planar 6-rings and highly curved 8-rings. 2_75, 2_6 or 2_76 are not expected to be chemically feasible.

## 3- and 4-ring family

These eight structures are grouped together because they contain both 3 and 4membered rings, although in other ways they are fairly different. Seven structures are cubic, and five have framework densities lower than $14 \mathrm{~T} / 1000 \AA^{3}$, illustrating the tendency of rare (i.e., the opposite of dense) structures to contain small rings. 2_99 (Figure 14a) can be described as a network of corner-sharing 3 and 4-rings, part of which is the unit illustrated in Figure 14b, a 3-ring linked to three 4-rings. Three types of cages can be found: the $\left[3^{8} 8^{6}\right]$ (truncated cube), shown in Figure $14 \mathrm{c},\left[4^{10} 7^{4} 8^{2}\right]$ units (not shown) and $\left[4^{8} 7^{12}\right]$ (Figure 14d). This cubic structure is feasible, $\vartheta=10.53$, but contains unusual 7-membered rings, even despite the largest pores being formed by 8rings. The somewhat similar 2_62 (Figure 14e), which has $\vartheta=10.97$, also exhibits the truncated cube cage (Figure 14f), as well as D4R, $\left[4^{12} 8^{6}\right]$ cages similar to that found in

2_58 (Figure 6 k ) and the larger $\left[3^{8} 4^{6} 8^{12}\right]$ cage shown in Figure 14 g . 2_68 (Figure 14h) is tetragonal and has chains of 3-rings (Figure 14i) running along the (001) direction. It possesses cages (Figure 14j) linked through 10-membered ring pores, which form channels along (100) and (010). In a similar way to that observed for the remaining four structures in this family, $2 \_68$ has a low framework density of $13.08 \mathrm{~T} / 1000 \AA^{3}$ and $\vartheta=$ 13.82. 2_70 and 2_93 have similar framework densities to that of 2_68 (13.42 and 13.98, respectively) and $\vartheta=14.33$ and 28.25 , making these three structures interesting candidates as zeotypes. In 2_70 (Figure 14k), the 3-rings themselves form rings of eight via corner-sharing, which define chains of $\left[3^{8} 8^{6}\right]$ truncated cubes (shown looking down the body diagonal in Figure 141). The larger $\left[3^{8} 4^{6} 8^{12}\right]$ cages shown in Figure 14 m also describe a three-dimensional network. 2_93 possesses [34 $6^{4}$ ] cages, i.e., truncated tetrahedra (Figure 140), which link through shared 3-rings to form a body-centred cubic structure, describing the $\left[4^{6} 6^{32}\right]$ supercages shown in Figure 14p. Interestingly, despite its relatively low density, this structure does not contain rings larger than 6. 2_18, 2_28 and 2_5 have much lower framework densities ( $10.06,11.69$ and 7.28 , respectively) than conventional zeolites, and correspondingly are much less feasible as zeotype materials. They are built from quite simple motifs: in 2_18 (Figure 14q-s) double 4-rings are linked in a three-dimensional network by spiro-5 units (i.e., two 3-rings sharing a T-atom), to form a body-centred cubic structure; the basic unit of structure 2_28 (Figure 14t-v) is a pair of edge-linked 3-rings (or bridged 4-ring), with two of these units being shown in Figure $14 u$, together with two linking 4 -rings and the resulting large $\left[3^{12} 4^{12} 6^{6} 12^{8}\right]$ cavity in Figure 14 v ; 2_5 is homologous with 2_18 but central T-site of the spiro-5 units is in this case replaced by a tetrahedron of T-sites. These three structures are very open, with 2_18 and 2_5 accessible through puckered 18- and 24-membered rings, respectively (see the "cages" illustrated in Figure 14s and y), whereas 2_28 has 12-ring channels along all $\{111\}$ directions.

## [ $3^{2} 4^{3}$ ] D3R family

The common feature is a double 3 -ring unit, i.e., a trigonal prism or a $\left[3^{2} 4^{3}\right]$ unit, and we have assigned nine structures to this family. As in the previous family, many are of interest due to their low density, with the presence of small polyhedra being compensated by large supercages. While we believe that none is feasible in a traditional zeolite or AlPO composition, they may be well of interest in several areas of chemistry, for instance if it were possible to form the D3R unit as a precursor. All the structures are cubic and have at least $\mathrm{m}-3 \mathrm{~m}$ symmetry. Structure $2 \_43$ (Figure 15a) is the most
feasible ( $\vartheta=11.62$ ) and has D3R units attached to $\left[3^{4} 6^{4}\right]$ truncated tetrahedra to form tetrahedral units (Figure 15b). "Truncated cube" cages (see section 3.11) are present, as are the large $\left[4^{24} 6^{8} 8^{18}\right]$ cages shown in Figure 15c, and the largest accessible pore is an 8ring. In 2_64 (Figure 15d), the D3R are also attached to truncated cube cages, but the structure additionally contains alpha and $\left[4^{24} 6^{8} 8^{18}\right]$ Tschörtnerite (TSC) cages (Figure 15e-f). Again, despite a very low framework density (10.14, compared to 9.71 for 2_43), the pore system is only accessible though 8 -ring apertures. 2_23 (Figure 15 g ) has beta cages (Figure 15h) linked via D3R-4-ring-D3R bridging units. The large cavities (Figure 15i) have 16 -membered rings in all three directions. $2 \_26$ (Figure 15 g ) also has the same unit of two D3R linked though a 4-ring (as do 2_25 and 2_22), with alpha cages present, but the main pore system is defined by the tetrahedral $\left[3^{12} 6^{4} 12^{4}\right]$ and the larger $\left[4^{24} 8^{6} 12^{8}\right]$ cages (Figure 15k-l), which are linked through 12-ring pores. The latter cavity has the same topology as that found in structure 1_11.(Foster, et al. 2003) Structure 2_25 (Figure 15 m ) has a pore system connected through 12-ring apertures and contains not only FAU supercages and LTA alpha cages, but also the large $\left[4^{24} 8^{6} 12^{8}\right]$ cages (Figure 15n) which are found in the RWY structure, and correspond in a topological sense to truncated sodalite cages (each T-site of the sodalite cage is replaced by a 3-ring). 2_41 (Figure 15o) has similarities to $2 \_43$ as the D3R form an alternating network with truncated tetrahedra (as in Figure 15b). In this case, the units form a continuous network, thereby defining very large $\left[4^{36} 6^{24} 8^{6} 12^{8}\right]$ cages shown in Figure 15p, which is reflected in its low framework density $\left(\mathrm{F}_{\mathrm{D}}=8.99 \mathrm{~T} / 1000 \AA^{3}\right)$. 2_22 (Figure 15 q ) is also of very low density ( $\mathrm{F}_{\mathrm{D}}=9.70 \mathrm{~T} / 1000 \AA^{3}$ ), and has the D3R connected so as to define D8R (Figure 15r). The already discussed large $\left[4^{24} 8^{6} 12^{8}\right]$ and RWY cages (Figure 15s-t) are present, and linked through 12-rings. Finally 2_4 and 2_8 (Figure $15 u$ and $x$ ) are among the least dense of all the binodal simple tile structures, with $\mathrm{F}_{\mathrm{D}}$ of 5.39 and $6.48 \mathrm{~T} / 1000 \AA^{3}$ respectively. The basic building unit of $2 \_8$ is two D3R stacked with an intervening D4R (Figure 15v). In 2_4 the intermediate unit is absent, and D3R units join directly through a shared 4ring (Figure 15y). In both cases, very open cavity systems are constructed by connection of these units, as seen in Figure 12w-z.

## 3-ring family

This family of eight structures is characterised by the presence of 3-rings. Five structures contain pairs, or longer chains, of 3-rings which share one T-atom, and therefore contain the spiro-5 unit (Baerlocher, et al. 2001). Two of the structures also contain 4-rings, but have more affinity with the others in this family, rather than with
the more symmetric structures in previous families. As expected, several of the structures are of low density, but none would be expected to be realisable as a "conventional" zeolite, 2 _71 being the most feasible with $\vartheta=17.07$. In 2_71 (Figure 16a), 3 -rings themselves form rings of six (Figure 16b), with the structure also containing elongated cages having 8 -rings as their largest pore, these cages being of somewhat irregular appearance (Figure 16c). The basic unit of $2 \_69$ is a pair of edge-sharing 3rings (or bridged 4-ring), which link as shown in Figure 16e. These larger units then connect to define the hexagonal channel system (Figure 16d), of which a puckered 12ring forms the characteristic pore. 2_65 (Figure 16f) also contains loops of six 3-rings (Figure 13g), virtually identical in structure to those present in 2_71. However, the structure is much more open ( $\mathrm{F}_{\mathrm{D}}=12.28$, compared to 17.38 for 2 _ 71 ), containing a three-dimensional network of 10 and 12-ring pores (the latter shown in Figure 16h), defined by the 3-ring network. 2_44 (Figure 16i) is another very open structure ( $\mathrm{F}_{\mathrm{D}}=$ 10.36), with a three-dimensional network of corner-sharing 3-rings defining the small [ $3^{4} 6^{4}$ ] cages shown in Figure 16j, as well as large cavities linked through 12-rings. 2_12 has unusual chains built up from pairs of edge-sharing 3-rings (Figure 161). This structure is tetragonal and has large cross-linked channels extending in two dimensions, delineated by puckered 14 -membered rings. $2 \_29$ (Figure 16 m ) is an unusually complex cubic structure, with 3 and 4-rings linked together as shown in Figure 16n: pairs of 3rings are formed which edge-share (there are no spiro-5), and these pairs are further connected by distorted 4 -rings. Both 9 -rings and 12-rings are thus formed (Figure 160p), with former forming channels along the (111) direction. Uniquely for this family, in 2_105 (Figure 16q), the 3-rings do not directly link into chains or pairs through the sharing of T-atoms, but rather connect through O bridges to define 5-rings (Figure 16r). This ideally trigonal structure (but which optimises in space group $P 1$ ) has large-pore type channels defined by puckered 12-rings. Finally, 2_9 (Figure 16s) has "H-shaped" building units in which 4-rings share edges with pairs of 3-rings (Figure 16t). On a larger scale, the structure has unidirectional channels defined by puckered 18membered rings, similar to those present in 2_30 (Figure 131).

## [34] family

The common feature of this family is a $\left[3^{4}\right]$ unit, sometimes known as the "supertetrahedron" or tetrahedron of tetrahedra. As already mentioned, this unit is unknown in zeolitic oxide materials, but is present in some sulphide materials, including the zeotypic RWY structure and the compound $\mathrm{Na}_{2} \mathrm{Si}_{2} \mathrm{~S}_{5} .2$ _16 (Figure 17a-b),
one of the few structures here containing 7 -rings, is characterised by its $\left[3^{8} 4^{2} 7^{8} 8^{4}\right]$ cage shown in Figure 17b. Each of the eight 3-rings forms part of a [3 ${ }^{4}$ ] unit, shared with three other cages. This structure is the most "feasible" of this family, with $\vartheta=36.19$. An alternative description of the structure lies in the fact that it can be derived from the clathrasil-like 2_117 (see the "orphan" section below) by replacement of one of the unique types of T-site by a tetrahedron of T-sites. In a similar way, $2 \_14$ (Figure 17c-d) has only one type of "larger" cage, $\left[3^{8} 4^{2} 6^{4} 8^{8}\right]$, and the whole structure can be thought of in terms of the sodalite framework, but with one third of the T-sites replaced by [3 ${ }^{4}$ ] supertetrahedra. 2_15 (Figure 17e-f) is also related to the sodalite structure, though now with half of the original T-sites replaced by the [ $3^{4}$ ] units, creating $\left[3^{12} 6^{6} 9^{8}\right]$ cages. $2 \_10$ (Figure $17 \mathrm{~g}-\mathrm{i}$ ) can be derived from the RHO zeolite structure by replacement of all Tsites by $\left[3^{4}\right]$ tetrahedra. As a result it possesses very large cages linked via double 16membered rings (Figure 17i). Finally, structure 2_7, being the least dense of this family ( $\mathrm{F}_{\mathrm{D}}=8.60$ ), has $\left[3^{4} 6^{4}\right]$ units ("truncated tetrahedra") linked via chains of 4-rings and $\left[3^{4}\right]$ units. This very open cubic structure has 16-MR pores in all three dimensions.

## Orphan structures

Some structures cannot be categorised in our "family" system.
2_117 (Figure 18a-b) is a highly feasible ( $\vartheta=1.22$ ) clathrasil-type structure containing 4,5 and 6 -rings. It has only one type of cage, $\left[4^{2} 5^{8} 6^{4}\right]$, which is shown in Figure 18b.

2_113 (Figure 18c-d) also has only one type of cage, made up of 4, 5 and 6-rings. In this case, however, the $\left[4^{4} 5^{4} 6^{4}\right]$ cage is chiral, with the structures being built up from alternating layers of the two enantiomeric forms of the cage. Furthermore, the structure is also feasible as a zeolite with $\vartheta=5.32$.

2_96, another feasible zeolite structure ( $\vartheta=5.45$ ), is unusual as it contains small [ $4^{5} 5^{2} 6^{2}$ ] cage units (Figure 18e) interconnected through shared 4-rings to form a threedimensional network (Figure 18f), thereby defining the $\left[5^{12} 6^{20}\right]$ cage shown in Figure 18 g (which also appears in structure 2_97).

2_67 (Figure 18h-j) is built up from twisted sheets of 4-membered rings, which include "squares" of four 4-rings (Figure 18i). The large cages (Figure 18j), reminiscent of those of faujasite, define a three-dimensional network of 12-membered ring pores. For this structure $\vartheta=10.27$.

2_37 (Figure 18k-m). The basic building unit is the D4R, which links via 4-rings to create double 12-membered rings (Figure 181), which are in turn linked into large
[ $4^{36} 8^{4} 12^{8}$ ] supercages (Figure 18 m ). These supercages have tetrahedral symmetry, with four puckered 12 -rings and four 12 -rings which are almost planar. Overall, this cubic structure is quite open with $\mathrm{F}_{\mathrm{D}}=12.58 \mathrm{~T} / 1000 \AA^{3}$, but is of intermediate feasibility $(\vartheta=$ 18.50).

2_48 (Figure 18n-p) also contains D4R units, which, together with elongated D8R, form a three-dimensional network (Figure 180) having large $\left[4^{24} 8^{6} 9^{8}\right]$ cages as depicted in Figure 18p; a 9-ring thus defines the largest pore present in the structure, which again is feasible $(\vartheta=19.09)$, though we predict not as a "conventional" zeolite.

2_52 (Figure 18q-s). Another cubic structure containing D4R, which in this case form "butterfly-like" units (Figure 18q) with four 4-rings. [ $\left.4^{24} 6^{4} 12^{4}\right]$ FAU supercages (Figure 18s) are also present, and so the structure has a network of 12 -ring pores. $\vartheta=$ 20.93.

2_79 (Figure 18t-v) possesses a three-dimensional network of distorted sodalite cages, linked as shown in Figure 18u. The structure also contains D6R and D8R, the latter separating LTA cages as depicted in Figure 18v. For this structure $\vartheta=23.48$, which renders the remaining members of this family increasingly less probable candidates for zeolite synthesis.

2_46 (Figure $18 \mathrm{w}-\mathrm{y}$ ) is similar to $2 \_67$ as it contains no small cages or prismatic units, but can rather be described in terms of a continuous sheet of 4 - and 6 -rings, a section of which is shown in Figure 18x. Topologically, the sheet is equivalent to the Schwarz D surface (Gandy, et al. 1999), and as a consequence the pore system is divided into two identical but non-intersecting volumes, with the centres of the large cages forming two interpenetrating diamond lattices. These cages, shown in Figure 18y, are connected through 12-ring apertures.

2_94 (Figure 18 z and aa). This structure contains $\left[3^{4} 6^{4}\right]$ truncated tetrahedra, distorted sodalite cages, and larger cages with 3- and 6-rings, seen in Figure 18aa. The ideal symmetry of the structure is Fd-3m. However, in silica form, it appears highly strained in this symmetry, preferring to minimise in space group C121, hence giving rise to the somewhat distorted appearance.

Like 2_94, 2_98 (Figure 18bb-cc) is a dense structure ( $\mathrm{F}_{\mathrm{D}}=20.69 \mathrm{~T} / 1000 \AA^{3}$ ). Based on edge-sharing chains of 4-rings, the structure has as its largest pore the twisted 8-ring shown in Figure 18cc.

2_111 (Figure 18dd-ff) is both highly dense ( $22.87 \mathrm{~T} / 1000 \AA^{3}$ ) and unfeasible as a zeolite $(\vartheta=43.36)$. However, it is remarkable as it contains 3 -, 5 -, 6 - and 7 -rings, from
which a 7-ring is illustrated in Figure 18ff. A characteristic feature of 2_111 is the "cup" unit shown in Figure 18ee, composed of a 3-ring and three 5-rings.

Finally, 2_42 (Figure 18gg-ii) has triple 8-membered rings (Figure 18hh), as well as $\left[4^{4} 5^{4}\right]$ units. Although of relatively high density (17.94), it still has large $\left[4^{24} 5^{24} 8^{6} 12^{8}\right]$ cavities (Figure 15ii), linked into a three-dimensional network through puckered 12membererd rings.

## Conclusions

We have evaluated and characterised 109 hypothetical zeolite structures, of which 98 do not correspond to known zeotype frameworks. Among these are many very interesting candidates for zeolite synthesis. Some of the most feasible as conventional aluminosilicates or AlPOs are those in the ABC-6 family, composed principally of 4and 6-rings, though from the point of view of porosity, the more likely structures will be at best small-pore zeolites, having no aperture larger than the 8 -ring. Other promising candidates come from structures which similarly have features in common with known zeolites, such as those in the AWW and SAS families (Figures 3 and 5), where cages stack through shared 8-rings. Again, 4 and 6 -rings predominate, with the 8 -ring being the limiting aperture in all cases, as it is for the more feasible structures in the $\left[4^{2} 5^{6}\right]$ family (Figure 6). At the other end of the scale, many very open structures also exist. These illustrate well the principle originally due to Meier (Brunner \& Meier 1989) that less dense structures invariably require a greater proportion of "small" (3- or $4-)$ rings as compensation. Here, we can extend this to state that larger cavities also require the presence of much smaller cages. Hence we find large-pore structures containing $\left[3^{4}\right]$ units (Figure 14), double-3-rings (Figure 12) and double 4-rings (e.g., Figures 7 and 8) 3-rings as well as pairs and chains of 3- and 4-rings. In terms of aluminosilicate (and aluminophosphate) zeolites, these structural units, particularly those containing 3-rings, are by-and-large disfavoured due to the strain imposed on the $\mathrm{TO}_{4}$ tetrahedra. In fact it is apparent that feasibility decreases markedly as more 3-rings are connected together with, for example, structures containing [ $3^{4}$ ] units having higher values than those containing only spiro-5 units. The most viable 3-ring structures are those in which the 3-rings are isolated from one another. The best example is 2_103 which contains the $\left[3^{2} 5^{6}\right]$ unit (Figure 5b), reminiscent of the $\left[3^{1} 4^{3} 5^{3}\right]$ units in the MEI structure. 2_103 is the most feasible large-pore zeolite among our 109 structures. Similarly, although 4-rings are found in the most feasible structures, agglomerations of
these units, obtained for example by stacking prismatic units such as D4R and D6R, result in decreasing likelihood (though individual D4R and D6R are tolerated, unlike D3R).

Having discounted many of the more open structures as potential zeolites on account of the presence of these small units, we do not exclude the possibility that these topologies could be possible in other chemical compositions where the local coordination environments are less constrained. Indeed, if we could construct units such as the D3R or the supertetrahedron as precursor species, many open framework architectures could be synthesized.

Figure 1. Framework energy, $\mathrm{EF}_{\mathrm{F}}(\mathrm{kJ} / \mathrm{mol})$, with respect to $\alpha$-quartz, versus framework density (Si atoms per $1000 \AA^{3}$ ) for (a) and (b) all known zeolitic structure types; (b) and (d) hypothetical binodal zeolitic structures.

Figure 2. Accessible volume ( $\AA^{3}$ per Si atom) versus framework density for (a) all known zeolitic structure types; (b) hypothetical binodal zeolitic structures. Inset in (b) shows structures with accessible volumes below $30 \AA^{3}$ per Si atom.

Figure 3. Framework energy with respect to $\alpha$-quartz versus accessible volume ( $\AA^{3}$ per Si atom) for (a) all known zeolitic structure types; (b) and (c) hypothetical binodal zeolitic structures. Hypothetical structures of particular chemical interest are identified in (c).
