25 26 **Abstract**

27 The Tibetan Plateau is generally considered to be a significantly clean area owing to its high altitude;
28 however, the transport of atmospheric pollutants from the Indian subcontinent to the Tibetan Plateau has
29 infected the Tibetan environments. Nyingchi is located at the end of an important water vapor channel.
30 In this study, continuous monitoring of gaseous elemental mercury (GEM), gaseous oxidized mercury
31 (GOM), and particle-bound mercury (PBM) was conducted in Nyingchi from March 30 to September 3,
32 2019, to study the influence of the Indian summer monsoon (ISM) on the origin, transport and behavior
33 of mercury. The atmospheric Hg concentrations during the preceding Indian summer monsoon (PISM)
34 period ($1.20 \pm 0.35 \text{ ng m}^{-3}$, $13.5 \pm 7.3 \text{ pg m}^{-3}$, and $11.4 \pm 4.8 \text{ pg m}^{-3}$ for GEM, GOM, and PBM, respectively)
35 were relatively higher than those during the ISM period ($0.95 \pm 0.21 \text{ ng m}^{-3}$, $12.7 \pm 14.3 \text{ pg m}^{-3}$ and 8.8 ± 6.0
36 pg m^{-3}). The average annual total gaseous mercury concentration in the Nyingchi region was obtained
37 using a passive sampler as $1.12 \pm 0.28 \text{ ng m}^{-3}$. The GEM concentration showed that the sampling area was
38 very clean. The GEM has several patterns of daily variation during different periods. Stable high GEM

39 concentrations occur at night during PISM, which may be related to the nocturnal boundary layer. High
40 values occurring in the late afternoon during the ISM may be related to long-range transport. The results
41 of the trajectory model demonstrate that the sources of pollutants at Nyingchi are different under the
42 control of different airflow fields. During westerly circulation, pollutants mainly originate from northeast
43 India or Nepal. During the ISM period, the pollutants mainly originate from northeast India, or the Bay
44 of Bengal, and the Indian Ocean. The strong precipitation and vegetation effects on Hg during the ISM
45 resulted in low Hg concentrations transmitted to Nyingchi during this period. Further, principal
46 component analysis showed that long-distance transport, local emissions, meteorological factors, and
47 snowmelt factors are the main factors affecting the local Hg concentration in Nyingchi.

48

49 **1. Introduction**

50 Mercury (Hg) is classified as a hazardous pollutant because it is bio-accumulative and toxic.
51 Generally, atmospheric Hg can be categorized into three major types: gaseous elemental mercury (GEM),
52 gaseous oxidized mercury (GOM), and particle-bound mercury (PBM) (Selin, 2009). The stable chemical
53 properties of GEM coupled with its long atmospheric lifetime (approximately 0.3 to 1 year) makes GEM
54 an important global pollutant (Selin, 2009;Travnikov et al., 2017). In contrast, GOM and PBM are easily
55 removed from the atmosphere through wet and dry deposition because of their chemical activity, and
56 have significant impacts on the local environment (Lindberg and Stratton, 1998;Seigneur et al., 2006).
57 Both GOM and PBM have complex fundamental physiochemical properties and may have complicated
58 relationships with other regional pollutants (Gustin et al., 2015). Understanding, identifying, and
59 characterizing Hg sources and their global and regional transport mechanisms is crucial for global
60 atmospheric Hg control and health effect research (UNEP, 2018). Since 2013, the Minamata Convention
61 was established to control the global mercury pollution (UNEP, 2013a). Monitoring atmospheric Hg is
62 an important prerequisite for implementing the convention. Currently, several Hg monitoring networks
63 and studies have been established to better understand atmospheric Hg cycling. The Atmospheric
64 Mercury Network (AMNet; Gay et al., 2013), Global Mercury Observation System (GMOS), and the
65 Canadian Atmospheric Mercury Network (CAMNet) are the main monitoring networks operating in
66 North America and Europe; majority of them only monitor GEM concentrations (Gay et al.,
67 2013;Sprovieri et al., 2013;Sprovieri et al., 2016;Kellerhals et al., 2003). Researchers worldwide have
68 also contributed to monitoring the data from different regions (Gustin et al., 2015;Jiang and Wang,
69 2019;Stylo et al., 2016). However, there exists some gaps in understanding the sources and transport of
70 atmospheric Hg in some remote areas, especially in harsh environmental areas where performing
71 monitoring is difficult.

72 Considering that GEM can be transported globally over long distances and that the transport
73 distances of GOM and PBM vary greatly in different environments, atmospheric Hg concentration
74 monitoring may not directly reflect the intensity of regional atmospheric Hg emissions. Our previous
75 study of the Qomolangma National Nature Preserve (QNNP) (Lin et al., 2019) demonstrated that the Hg
76 emitted from India can cross the Himalayas to reach the Tibetan Plateau. Further research on the
77 transboundary transport of Hg should be conducted to better understand the transport mechanisms. This
78 is particularly true in Asia, where the environmental pollution is generally severe. China and India are

79 reported to be the world's largest consumers of coal (BP Statistical Review of World Energy, 2018).
80 Considering that coal is the largest source of Hg in the atmosphere (approximately 86% of Hg comes
81 from fuel combustion (Chen et al., 2016)), both China and India have great Hg emission potential. Further
82 research on pollutant transport in Asia should be conducted to support policy development and
83 responsibility allocation.

84 The Tibetan Plateau, with an average elevation of more than 4,000 m above sea level, is a natural
85 barrier between inland China and the Indian subcontinent (Qiu, 2008; Lin et al., 2019). In the southern
86 part of the Tibetan Plateau, the Himalayas, with an average altitude of 6,000 m, can serve as a solid
87 barrier to pollutant transport. However, this barrier cannot completely block the transboundary
88 transportation of pollutants according to previous studies. The transboundary and long-distance transport
89 of pollutants across the Himalayas has attracted considerable attention (Wang et al., 2018; Zhang et al.,
90 2015a; Yang et al., 2018; Li et al., 2016; Feng et al., 2019; Zhu et al., 2019). Several studies have shown
91 that the transboundary intrusion of atmospheric pollutants through the Himalayas on the Tibetan Plateau
92 is crucial for many pollutants (Yang et al., 2018; Li et al., 2016; Zhang et al., 2015b; Pokhrel et al.,
93 2016; Lin et al., 2019). Zhang et al. (2017) studied short-lived reactive aromatic hydrocarbons and
94 indicated that the cut-off low system that have lower altitude in the Himalayas is a major pathway for
95 long-distance transport of aromatic hydrocarbons in the Tibetan Plateau. Persistent organic pollutants
96 have been reported to be transported to the interior of the Tibetan Plateau by traveling along valleys or
97 across ridges (Gong et al., 2019a). The transport of aerosols and organic pollutants along the most
98 important water vapor channel, the Yarlung Zangbu/Brahmaputra Grand Canyon (hereafter referred to as
99 the YZB Grand Canyon), has been observed (Wang et al., 2015; Sheng et al., 2013). Our previous study
100 in the QNNP, on the southern border of the Tibetan Plateau, proved that atmospheric Hg from the Indian
101 subcontinent can be transported across high-altitude mountains directly to the Tibetan Plateau under the
102 action of the Indian monsoon and local glacier winds (Lin et al., 2019). However, to the best of our
103 knowledge, the monitoring of the passage of atmospheric Hg in the water vapor channel—the YZB Grand
104 Canyon, into the Tibetan Plateau has not been conducted. Through the water vapor and airflow channel,
105 air masses carrying large amounts of water vapor as well as pollutants may enter Tibet, resulting in heavy
106 precipitation during the monsoon season. Huang et al. (2015) reported that the total Hg wet deposition
107 in Nyingchi, located in the YZB Grand Canyon, was lower than that in other Tibetan Plateau regions,
108 and the concentration was lower in the monsoon season than in the non-monsoon season. As an important
109 transport channel for summer monsoon moisture into China (Xu et al., 2020; Feng and Zhou, 2012; Yang
110 et al., 2013), the amount of water vapor transported into Tibet through this channel is considerable, and
111 the transport of pollutants needs further investigation.

112 In this study, we set up high-precision Hg species monitoring in Nyingchi, southeastern Tibetan
113 Plateau, covering both PISM and ISM periods. Hg passive sampling was also applied to cover the
114 monitoring of the entire year. To the best of our knowledge, this is the first monitoring study of
115 atmospheric Hg species in the most important water vapor channel of the Tibetan Plateau. To better
116 identify the sources of Hg pollution and potential pollution areas, we combined real-time Hg monitoring
117 data with backward trajectory analysis, cluster analysis, and potential source contribution function (PSCF)
118 analysis. We also collected other pollutant concentrations and rainfall data near the monitoring station

119 during the same period to better analyze the source and transport characteristics of Hg. By combining the
120 real-time monitoring data and model simulations, we attempted to better characterize the process of Hg
121 entering Tibet through the water vapor channel, which could allow researchers to further analyze the
122 transport of Hg from the Indian subcontinent into Tibet and provide scientific support for managerial
123 decision making.

124 **2. Materials and methods**

125 **2.1 Atmospheric Hg monitoring site**

126 Atmospheric Hg monitoring was performed at the South-East Tibetan Plateau Station for Integrated
127 Observation and Research of Alpine Environment (SET station, Figure 1) in Nyingchi, Tibet, China. The
128 SET station is located in the southeastern part of the Tibetan Plateau (29°45'59N, 94°44'16E, 3263 m
129 a.s.l.), in a water vapor transportation channel, from the Ganges River Plain to the Tibetan Plateau.
130 Nyingchi is mainly under the control of westerly winds (from September to April) and ISM (from May
131 to August), exhibiting sharp seasonal variations. The average annual air temperature is 5.6 °C. The
132 Tibetan Plateau is generally a moisture sink in summer (Feng and Zhou, 2012; Xu et al., 2020), with
133 climatological moisture originating from the Indian Ocean and the Bay of Bengal intruding into the center
134 of the Tibetan Plateau along the water vapor channels. The average annual precipitation is approximately
135 700-1000 mm at the SET station. During the westerly control period, the air masses are mainly from mid-
136 latitude inland areas with less water vapor, while during the ISM period, a large amount of water vapor
137 from the Indian Ocean enters Tibet. The precipitation begins at the foot of the YZB Grand Canyon and
138 is sustained along with the canyon into Tibet (Gong et al., 2019b), and the precipitation in the downstream
139 Motuo County is more than twice that of the Nyingchi area (Ping and Bo, 2018). The unique
140 geomorphological conditions and the effect of the strong monsoon have resulted in a unique high-altitude
141 distribution pattern of various biomes and vegetation in the area. The SET station is 75 km from Bayi
142 Town, where the capital of Nyingchi Prefecture is located, and 480 km from Lhasa, which is the capital
143 city of the Tibet Autonomous Region. Owing to the high altitude and harsh living environment, the
144 permanent population in Tibet is extremely small and only a few local pollutant emission sources have
145 been observed (UNEP, 2013b; UNEP, 2018).

146 **2.2 GEM, GOM and PBM active monitoring**

147 Real-time continuous measurements of GEM, GOM, and PBM concentrations were carried out
148 using Tekran Model 2537B, 1130, and 1135 instruments (Tekran Inc., Toronto, Canada) at the SET station
149 from April 1, 2019, to September 4, 2019, which could show the diurnal and daily changes in atmospheric
150 Hg concentration in detail. During the operation of the Tekran instruments, the sampling inlet was set at
151 ~1.5 m above the instrument platform (shown in Figure S1). Considering the high altitude at which the
152 instrument was installed, as well as to mitigate the impacts of low atmospheric pressures on the pump's
153 operation, a low air sampling rate of 7 L min⁻¹ for the pump model and 0.75 L min⁻¹ (at standard pressure
154 and temperature) for model 2537B were applied, based on the previous studies (Swartzendruber et al.,
155 2009; Zhang et al., 2015a; Zhang et al., 2016; Lin et al., 2019). Air was sucked from the atmosphere in the
156 Tekran instrument, and the Hg was divided into GOM, PBM, and GEM inside the instrument for analysis.
157 Every 60 min, GOM was enriched on a KCL-coated annular denuder, PBM was enriched on a quartz
158 fiber filter (QFF), and GEM was directly enriched on the gold tube of the Tekran 2537B. The collected

159 PBM and GOM were desorbed in succession to Hg(0) at temperatures of 800 °C and 500 °C in the
160 following hour, respectively. Hg(0) was then measured by cold vapor atomic fluorescence spectroscopy
161 (CVAFS) in the Tekran 2537B instrument. To ensure high data quality, the Tekran 2537B analyzer was
162 set to use the internal Hg source for automatic calibration every 23 h. The instrument was calibrated
163 using an external Hg source at the beginning and end of the monitoring period. The Tekran ambient Hg
164 analyzer has been described in detail in previous studies (Landis et al., 2002;Rutter et al., 2008;de Foy
165 et al., 2016;Lin et al., 2019). The monitoring data were also modified using the method from Slemr et al.
166 (2016) as previous studies suggested that there may be a low bias for low sampling loads (Slemr et al.,
167 2016;Ambrose, 2017).

168 **2.3 Passive sampling of GEM concentration**

169 Passive samplers were set up at the same station during and after the active monitoring period to
170 better reflect the long-term pattern of local GEM concentration changes from April 2019 to March 2020.
171 Sulfur-impregnated carbon (Calgon Carbon Corporation) was used as the sorbent for GEM (Guo et al.,
172 2014;Zhang et al., 2012;Tong et al., 2016;Lin et al., 2017). Passive samplers were deployed in triplicate
173 near the Tekran instrument at a height of ~2 m above the ground, and generally the passive samplers were
174 replaced three times per month. After sampling, all samplers were sealed in a three-layer zip-lock bag
175 and transported to the laboratory, where they were then measured with the DMA-80 (Milestone Inc.,
176 Itália). The passive sampling method has been successfully applied to the Tibetan Plateau (Guo et al.,
177 2014;Tong et al., 2016) and North China (Zhang et al., 2012) in past studies. The use and quality control
178 of the Hg passive sampler have been described in detail in our previous studies (Zhang et al., 2012;Guo
179 et al., 2014;Lin et al., 2017).

180 **2.4 Meteorological data and other pollutants data**

181 During the monitoring period, the local temperature (with a precision of 0.1 °C), relative humidity
182 (with a precision of 1%), wind speed (with a precision of 0.1 m s⁻¹), wind direction (with a precision of
183 1°), air pressure (with a precision of 0.1 hPa), solar radiation (with a precision of 1 W m⁻²), and UV index
184 (with a precision of 0.1 MEDs) were recorded at a 5-minute resolution by the Vantage Pro2 weather
185 station (Davis Instruments, USA).

186 Hourly measurement data of PM_{2.5}, PM₁₀, SO₂, NO₂, O₃, and CO concentrations and AQI index
187 were obtained from a nearby monitoring station in Nyingchi, which was hosted by the China Ministry of
188 Ecology and Environment and published by the China National Environmental Monitoring Center. The
189 measurements were conducted following the technical regulations for the selection of ambient air quality
190 monitoring stations (National Environmental Protection Standards HJ 664-2013) (Yin et al., 2019).

191 **2.5 Backward trajectory simulation**

192 To better understand the source of atmospheric Hg, the Hybrid Single-Particle Lagrangian
193 Integrated Trajectory (HYSPLIT) model was applied to calculate the backward trajectory many
194 atmospheric particles (Stein et al., 2015;Chai et al., 2017;Chai et al., 2016;Hurst and Davis, 2017;Lin et
195 al., 2019). HYSPLIT was developed by the US National Oceanic and Atmospheric Administration
196 (NOAA) and is a known tool for explaining atmospherically transported, dispersed, and deposited of
197 particles. The HYSPLIT model (<https://www.arl.noaa.gov/hysplit/hysplit/>) is a hybrid method that
198 combines the Lagrangian and Euler approaches. The Lagrangian method calculates the movement of

199 matter under the action of advection and diffusion, and the Euler method uses a fixed three-dimensional
200 grid to calculate the pollutant concentration. The backward trajectory simulation used Global Data
201 Assimilation System (GDAS) data with $1^\circ \times 1^\circ$ latitude and longitude horizontal spatial resolution and 23
202 vertical levels at 6 h intervals. The trajectory arrival height was set to 1000 m a.g.l. Every backward
203 trajectory was stimulated for 72 h at 6 h intervals, which can cover China, Nepal, India, Pakistan, and
204 the majority of western Asia. Cluster analysis was performed after the trajectory calculation. Cluster
205 analysis can summarize the concentrations of GEM and the main trajectories from all trajectories.

206 The PSCF model was used to calculate the conditional probability by calculating the endpoints of
207 the trajectory segment ending in each cell, and the PSCF links the residence time in upwind areas with
208 measured high concentrations (Ashbaugh et al., 1985; Hopke and Association, 2016). The value of PSCF
209 represents the possibility that emissions from the source area will affect the air quality of the sampling
210 site. In this study, we used PSCF to identify the possible source region of atmospheric GEM in Nyingchi.
211 The PSCF values were also scaled by an arbitrary weighting function to reduce uncertainty owing to the
212 low PSCF value (Polissar et al., 1999).

213 2.6 Principal components analyses

214 Principal component analysis (PCA) is a data reduction method that can group some measured
215 variables into a few factors that can represent the behavior of the whole dataset (Jackson, 2005). PCA
216 has been employed in many previous Hg studies to analyze the relationships between Hg and multiple
217 pollutants and meteorological variables (Brooks et al., 2010; Cheng et al., 2012; Liu et al., 2007; Zhou et
218 al., 2019). All variables were normalized by standard deviation prior to running the PCA. To ensure that
219 PCA is a suitable method for the data set, the Kaiser-Meyer-Olkin measure of sampling adequacy ($MSA >$
220 0.5) and Bartlett's test of sphericity ($p < 0.05$) tests were performed during the data analysis process.
221 Total variance and scree plots after rotation were used in the PCA analysis to determine the factor
222 numbers. Components with variance ≥ 1.0 were retained. Variables with high factor loadings (generally $>$
223 0.5) were used to interpret the potential Hg source.

224 3. Results and discussion

225 3.1 Species Hg concentrations in Nyingchi

226 During the whole monitoring period, the GEM, GOM and PBM concentrations at SET station were
227 $1.01 \pm 0.27 \text{ ng m}^{-3}$, $12.8 \pm 13.3 \text{ pg m}^{-3}$, and $9.3 \pm 5.9 \text{ pg m}^{-3}$ (mean \pm SD), respectively. Figure 2 shows the
228 GEM, GOM, and PBM concentrations and daily rainfall over the sampling period. Table S1 summarizes
229 the statistical metrics of species Hg, meteorological factors, and other pollutants. To further discuss the
230 patterns of Hg concentrations, the entire monitoring period was divided into the PISM period (before
231 May 1) and the ISM period. The ISM period was further subdivided into three periods (ISM1 – ISM3)
232 according to changes in precipitation. The atmospheric Hg concentrations during the PISM period
233 ($1.20 \pm 0.35 \text{ ng m}^{-3}$, $13.5 \pm 7.3 \text{ pg m}^{-3}$, and $11.4 \pm 4.8 \text{ pg m}^{-3}$, for GEM, GOM and PBM respectively) were
234 higher than those during the ISM period ($0.95 \pm 0.21 \text{ ng m}^{-3}$, $12.7 \pm 14.3 \text{ pg m}^{-3}$, and $8.8 \pm 6.0 \text{ pg m}^{-3}$, for
235 GEM, GOM and PBM respectively). During the PISM period, the locally monitored GEM concentrations
236 decreased continuously as the Indian monsoon developed and intensified (Figure 2), which may indicate
237 a change in the local Hg source as the decisive wind field changes from westerly to Indian monsoon.
238 GEM concentrations remained relatively stable during ISM1 and ISM2 (0.92 ± 0.23 to $0.92 \pm 0.18 \text{ ng m}^{-3}$),

239 which may indicate that the source of GEM was relatively stable during this period. However, at the end
240 of the monsoon (ISM3), the GEM concentration started to increase gradually to $1.04 \pm 0.21 \text{ ng m}^{-3}$. There
241 was no significant correlation between GEM concentration and precipitation during the ISM period,
242 which may be due to the stable chemical properties of GEM because the air mass sources are relatively
243 stable during the ISM period (Horowitz et al., 2017), while GOM and PBM concentrations are strongly
244 influenced by precipitation (Figure 2). With the increase in rainfall from 113.75 mm during ISM1 period
245 to 373.28 mm during ISM2 period, the concentrations of GOM and PBM decreased sharply from
246 $15.4 \pm 7.9 \text{ pg m}^{-3}$ and $18.2 \pm 29.2 \text{ pg m}^{-3}$ to $7.9 \pm 3.4 \text{ pg m}^{-3}$ and $13.5 \pm 5.5 \text{ pg m}^{-3}$, respectively. The
247 considerable precipitation increase may be responsible for the rapidly reduced GOM and PBM
248 concentrations, as they are easily deposited in the atmosphere with precipitation (Lindberg and Stratton,
249 1998; Seigneur et al., 2006). In a previous study, Huang et al. (2015) found that even with heavy rain
250 during the monsoon period, the total Hg concentration in precipitation in the SET region was small but
251 still considerable, suggesting that there may be a stable source of Hg in the SET region during the ISM
252 period.

253 Figure 3 shows the results of the GEM concentrations obtained through passive samplers throughout
254 the year. The average GEM concentration is $1.12 \pm 0.28 \text{ ng m}^{-3}$, which is slightly higher than the average
255 GEM concentration during the Tekran monitoring period. The average GEM concentration is lower
256 ($1.02 \pm 0.09 \text{ ng m}^{-3}$) during the ISM control period (from May to August) and higher during the westerly
257 circulation control period ($1.16 \pm 0.32 \text{ ng m}^{-3}$); however, the GEM concentration during westerly
258 circulation control period has large fluctuations. Since there are almost no local industries and less human
259 activity in Nyingchi, this difference may indicate a higher input of pollutants introduced by westerly
260 circulation. For the variation throughout the year, the GEM concentration in May and June is the lowest
261 with an average concentration of only $0.97 \pm 0.18 \text{ ng m}^{-3}$, while November and December have the highest
262 GEM concentrations ($1.24 \pm 0.37 \text{ ng m}^{-3}$).

263 Table 1 summarizes the GEM, GOM, and PBM concentrations from research papers of high-altitude
264 regions around the world. Compared to other high-altitude sites, the Hg concentrations in the SET region
265 were relatively low and did not reach the average Hg concentration level in the Northern Hemisphere (~
266 $1.5\text{--}1.7 \text{ ng m}^{-3}$). Compared to previous studies of high elevation (> 2000 m a.s.l) regions, only Concordia
267 Station in Antarctica had lower GEM concentrations than those observed at the SET station. Ev-K2, Nam
268 Co, Qomolangma, and Shangri-La, the nearest monitoring stations to the SET station and at higher
269 altitudes, had higher GEM concentrations than those at the SET station. In particular, the GEM
270 concentration at Shangri-La was more than two-fold of that at the SET station. The differences in the
271 GEM concentrations among them may be mainly due to their different climatic conditions and different
272 monsoon control zones, which result in different pollutant source regions and air mass transport
273 trajectories. The Shangri-La station may be influenced by anthropogenic emissions within and outside
274 China, and therefore, has higher GEM concentrations. For Ev-K2 and Qomolangma stations, which are
275 under the influence of the ISM, they may be directly exposed to air masses with high concentrations of
276 pollutants transported from India and Nepal. Although there are violent deposition processes during the
277 climbing process to both Ev-K2 and Qomolangma stations, some Hg may survive reach the stations (Lin
278 et al., 2019). The GOM concentrations at the SET station were approximately at the average level among

279 the monitored sites. PBM concentrations were relatively low at the SET station, which may be due to the
280 high rainfall in the YZB Grand Canyon, easily washing away particulate Hg by rainwater.

281 The lower GEM concentrations during the ISM period may indicate that the pollutant sources of the
282 SET region changed with the weakening of the westerly circulation and the strengthening of the Indian
283 monsoon. In previous studies (Lin et al., 2019; Gong et al., 2019a; Wang et al., 2015), it is generally
284 believed that pollutants from the heavily polluted Indian subcontinent may be transported to the Tibetan
285 Plateau under the action of ISM, resulting in increased local pollutant concentrations on the plateau. This
286 was verified at the Qomolangma, Nam Co, and Mt. Ailao stations, where GEM concentrations were
287 higher during the ISM period than the PISM period (Lin et al., 2019; Yin et al., 2018; Zhang et al., 2016).
288 However, in our study, the SET station observed lower species Hg concentrations during the ISM than
289 the PISM period. For GEM, the decrease in concentration may be due to the absorption effect from the
290 dense vegetation during the monsoon period (Fu et al., 2016), while air masses from the Indian Ocean
291 bring large amounts of halogens, which may react with and deplete GEM. For GOM and PBM, increased
292 concentrations were observed during the ISM1 period, whereas their concentrations decreased sharply
293 during the ISM2 and ISM3 periods. The decreases in GOM and PBM concentrations may be mainly due
294 to the rapid increase in local precipitation during the Indian monsoon period, which starts after the
295 monsoon enters China from northwestern India. A large amount of water vapor from the Indian monsoon
296 climbs more than 3,000 m within ~100 km in the YZB Grand Canyon, producing considerable
297 precipitation. Therefore, GOM and PBM may settle during transportation and are unable to reach the
298 Nyingchi area.

299 **3.2 Diurnal Variation**

300 Figure 4 shows the diurnal variation of species Hg and the concentrations of other pollutants during
301 the entire monitoring period. In general, the species Hg concentrations varied significantly during the
302 PISM period, and the diurnal variation was relatively small after entering the ISM period. During the
303 PISM period, the GEM concentrations were relatively low during the daytime (average 1.07 ng m^{-3} from
304 11:00 to 18:00), gradually accumulated after sunset, and finally reached a relatively stable high value
305 (average 1.26 ng m^{-3}) at night. During the ISM period, the GEM concentration variation pattern was not
306 as pronounced as during the PISM period, with the lowest GEM concentration of the day usually
307 occurring around sunrise ($0.83, 0.80, 0.88 \text{ ng m}^{-3}$ for ISM1-3, respectively). During ISM1, the GEM
308 concentration reached a high value around 9:00 a.m., fluctuated less during the daytime, reached a
309 maximum value in the evening, and gradually dissipated in the early morning. During ISM2, the
310 maximum value was reached at approximately 16:00, was more stable in the evening, and gradually
311 dissipated in the early morning. During ISM3, the maximum value was reached at approximately 20:00
312 and dissipated in the early morning. The average of the daily maximum values were 1.04, 1.00, 1.16 ng
313 m^{-3} for ISM1-3 periods, respectively. After midnight, GEM concentrations gradually decreased. In
314 general, the daily variation of GEM in previous research were about $0.2\text{-}0.9 \text{ ng m}^{-3}$ globally, and were
315 lower at the SET site ($0.21, 0.20, 0.28$ for ISM1-3 periods, respectively). For GOM and PBM, the diurnal
316 variations showed U-shaped variation patterns during the PISM period. During this period, the
317 concentrations of GOM and PBM reached low values between 10:00 and 14:00, then gradually
318 accumulated and peaked around midnight. After midnight, the concentration gradually decreased to its

319 lowest point. During the ISM1 period, GOM and PBM concentrations were higher in the afternoon and
320 evening, and showed a decreasing trend after midnight. During ISM2-3, GOM and PBM did not show
321 clear daily variation patterns. Except for the ISM2 period, there was little difference between GOM and
322 PBM concentrations during the other periods, which may be due to similar sources and behavioral
323 patterns in the environment. In contrast, during the ISM2 period, more precipitation (Figure 2) led to a
324 sharp decrease in PBM concentrations, and it is speculated that GOM may have additional sources during
325 this period.

326 Compared with other Hg monitoring in previous studies, some diurnal variation trends of Hg at the
327 SET site were unique. In previous studies (Sprovieri et al., 2016; Yin et al., 2018; Zhang et al.,
328 2015a; Zhang et al., 2016; Fu et al., 2012; Fu et al., 2010; Lan et al., 2012), a common pattern of highest
329 concentration around noon and lowest concentration before sunrise was mostly observed. The decrease
330 in GEM concentration at night may be due to the chemical dissipation of GEM within the stable nocturnal
331 boundary layer, or deposition in the effect of dew (Mao et al., 2008; Kim, 2010). After sunrise, partial
332 GEM re-emission occurs in the sunlight, along with the mixing effect of the residual boundary layer
333 downward, which may lead to an increase in GEM concentration (Mao and Talbot, 2012; Selin et al.,
334 2007; Weiss-Penzias et al., 2009; Talbot et al., 2005). The height of the boundary layer increases after
335 noon during the daytime, which produces dilution of GEM at the surface and may be the reason for the
336 decrease in GEM concentration in the afternoon. The GEM diurnal variation pattern at the SET is
337 particularly special during the PISM period, while a similar variation pattern was also observed at the
338 Qomolangma site in our previous research (Lin et al., 2019), which is another high-altitude site with a
339 sparse population and rare industry. This similar pattern suggests that they have a similar mechanism of
340 GEM diurnal variation. Considering that neither site has an obvious local source of GEM, the variation
341 in GEM concentrations may only be subject to these mechanisms. Similar to the study of Qomolangma,
342 the variation in the boundary layer height may be one of the reasons for the diurnal variation of GEM
343 concentration in the SET region. The stable and low height nocturnal boundary layer at night causes the
344 GEM concentration to gradually concentrate, and the boundary layer gradually increases to a higher
345 altitude after sunrise. The gradual increase in GEM concentration during the daytime may be due to the
346 reduction of GOM from nearby local snowy mountains (Holmes et al., 2010) or the field GEM source
347 brought in by airflow (Lin et al., 2019). During the ISM period, the nighttime GEM dissipation may be
348 due to the fact that this area enters a rapid leaf-growing season (Fu et al., 2016) after entering the ISM
349 period, that the air masses from the Indian Ocean bring a large amount of halogens, and that depletion of
350 GEM occurs under the boundary layer at night.

351 **3.3 Source identification for atmospheric Hg in Nyingchi**

352 To further investigate the contributions of different sources to the SET site, air mass back trajectory
353 simulation and trajectory cluster analyses were performed. Figure 5 shows the cluster analysis results for
354 the PISM and ISM1-3 periods. Based on the results of the total spatial variation index, 3-5 clusters were
355 grouped for each period. Each clustered trajectory contained detailed information about the trajectory
356 from the source region to the SET site, the trajectory frequency during the period, and the concentrations
357 of the pollutants carried by the air mass when the trajectory arrives.

358 During the PISM period (Figure 5a, Table S2), the trajectories mainly originated from or passed

359 through Nepal, northeastern India, and central Tibet, and moved along the southern border of the
360 Himalayas Mountains. During this period, Nyingchi was mainly controlled by westerly circulation. The
361 two clusters with the highest concentrations (traj1 and traj2, with GEM concentrations at 1.21 and 1.20
362 ng m^{-3}) originated from or passed through central Tibet, accounting for 35.32% of all trajectories in this
363 period. Although the GEM concentrations of the two clusters were relatively high during this period, they
364 were still lower than the background GEM concentration in the Northern Hemisphere ($\sim 1.5\text{--}1.7 \text{ ng m}^{-3}$),
365 indicating that the air mass transported to SET station is relative clean. Traj0, from the southern border
366 of the Himalayas, was relatively high in proportion (with a frequency of 61.28%), mainly controlled by
367 the southern branch of the westerly circulation, and has a relatively low concentration (1.05 m^{-3}). This
368 cluster made a turn in the Bay of Bengal and began to ascend toward the Tibetan Plateau, according to
369 UNEP reports (UNEP, 2018; UNEP, 2013b), Hg emission intensities along the trajectory paths were weak.
370 In addition, the air mass arriving at the SET site during this period came from the interior of the continents
371 and contained less water vapor, which may lead to less precipitation and less Hg deposition during the
372 transboundary transport.

373 During the ISM period (Figure 5b-d), the trajectory of arrivals at the SET site changed significantly
374 with the onset and rise of the Indian monsoon. The trajectory path gradually shifted from the southern
375 margin of the Himalayas to the Bay of Bengal. As the source of the air mass changes and the monsoon
376 enters the plateau, it is possible that the concentration of pollutants decreases because of the change in
377 the source region. Because the air mass originated from the Indian Ocean, the concentration of water
378 vapor should increase significantly. During the ISM1 period (Figure 5b, Table S2), both the rising
379 monsoon and the tail of the westerly circulation control the region, causing the transported air masses to
380 exhibit complex trajectories and combined effects. The cluster with the highest concentration (traj2, 0.96
381 ng m^{-3} , and 29.0%) mainly came from or passed through central India. The trajectory with the largest
382 proportion (traj0, 61.45%) had a relatively short path, mainly from northwest India and northern Bay of
383 Bengal, and showed relatively lower concentrations (0.88 m^{-3}). Based on the existing atmospheric Hg
384 emission inventories (Simone et al., 2016; UNEP, 2018; UNEP, 2013b), the Hg emission intensities of
385 northwest India and the Bay of Bengal are very low, which may be the reason for the low GEM
386 concentrations in this cluster. It is noteworthy that although the concentrations were low throughout the
387 period, the trajectories of the different sources showed large concentration differences. Figure S2 shows
388 all the trajectories during the ISM1 period and the GEM concentrations they represent. GEM
389 concentrations are still high in trajectories originating from or passing through northern India and Nepal,
390 which may be related to the high intensities of Hg emissions from anthropogenic sources in those regions
391 (De Simone et al., 2015) and wildfire events (Lin et al., 2019; Finley et al., 2009). Trajectories from
392 central Tibet also have high concentrations, which may be caused by local emissions such as yak dung
393 burning (Lin et al., 2019; Huang et al., 2016), and the local sources do not pass through the areas with
394 high deposition.

395 During the ISM2 period (Figure 5c, Table S2), a typical period of Indian monsoon control, almost
396 all trajectories came from or passed through the southern part of the SET site and were influenced by the
397 monsoon. Only about 5.4% of the trajectories originated from central Tibet with very low GEM
398 concentration (traj0 with 0.81 ng m^{-3} and 3.17%, traj4 with 1.00 ng m^{-3} and 2.24%). Other trajectories

399 were almost identical, but with different track lengths, and showed low GEM concentrations (traj1 with
400 0.90 ng m^{-3} and 70.34%, traj2 0.94 ng m^{-3} and 19.40%). During this period, trajectories that originated
401 in the Indian Ocean brought a large amount of water vapor and caused considerable precipitation during
402 transportation. The Hg carried in the air masses may have been heavily deposited during transport. At
403 the same time, the areas through which the trajectory passed were sparsely populated and underdeveloped
404 and were unable replenish Hg to the air masses. The range of atmospheric mercury concentrations during
405 the ISM2 phase was extremely small (Figure 2), which may indicate that under the strong control of the
406 Indian monsoon, the main source region, transport path, and mechanism of transportation during this
407 period remain stable. Compared with the ISM1 period, although many wildfires existed during this period,
408 the large amount of precipitation may have prevented the dispersion of these pollutants from the wildfire
409 sites.

410 During the ISM3 period (Figure 5d, Table S2), the Indian monsoon remained controlling this region,
411 but its intensity weakened, and the precipitation in the Nyingchi area was greatly reduced. Most of the
412 trajectories still came from northwest India (traj0 and traj3, 46.2% and 45.11%, respectively), and the
413 trajectories remained short. But the GEM concentration at SET increased compared with the ISM1-2
414 period (average at 0.92 ng m^{-3} in ISM1 and ISM2 to 1.04 ng m^{-3} in ISM3 period). At the end of the ISM3
415 period, the GEM concentration showed an upward trend (Figure 2), which may be due to the weakening
416 of monsoon control. A shortened trajectory at the end of the monsoon period was also observed in another
417 study at a nearby site (QNNP) (Lin et al., 2019), which may indicate the withdrawal of the monsoon.

418 To visualize the potential Hg source areas during the monitoring period, PSCF simulation was also
419 applied in this study in combination with the backward trajectories and detailed Hg monitoring at the
420 SET station. Figure 6 shows the potential source regions of Hg during the PISM and ISM periods. The
421 potential source areas of Hg did not change significantly throughout the study period and were mainly
422 concentrated in the YZB Grand Canyon and the southern plains of the Canyon, south of Nyingchi. Due
423 to the complex terrain, even the strong Indian monsoon can linger in the canyon for a long time because
424 of the elevation rise and tortuous path. It is worth noting that heavy precipitation began when the
425 monsoon began to climb and continued until the end of climbing. Therefore, before arriving at the SET
426 station, Hg underwent multiple deposition processes. This may be the reason for the extremely low Hg
427 concentration at the SET station during the monsoon period.

428 **3.4 Hg concentration controlling factor indicated by PCA results in Nyingchi**

429 Overall, 4-5 factors were resolved for each period from the PISM to ISM3 periods. Some factors
430 are unique to each period, and certain factors are found throughout the monitoring period. Table 2 lists
431 the four underlying PCA factors for important Hg-related components. They were assigned as long-
432 distance transport, local emissions, meteorological factor, and snow melt factor.

433 The long-distance transmission factor (F1) found in the PISM and ISM3 periods mainly contain
434 GEM, wind speed, CO (positive loading), temperature, and SO_2 (negative). GEM could be considered
435 an indicator of long-distance transportation due to its long lifetime in the atmosphere, especially when
436 GOM and PBM are not significant in this factor. This factor indicates that the long-distance transportation
437 of GEM may mainly occurs in the pre-monsoon and the end of the monsoon period, which is similar to
438 the trajectory analysis in Section 3.3. The negative correlation between GEM and temperature may

439 indicate that the long-distance transport of GEM during the PISM period occurs mainly during periods
440 of lower temperatures. Compared with the diurnal variation of GEM during the ISM period (Figure 4),
441 it is possible that the increasing GEM concentration in the evening in the PISM period is mainly due to
442 the long-distance transportation of GEM.

443 Factor 2 involved GOM and PBM (high positive loading) in each period, mainly with positive O₃,
444 PM₁₀, PM_{2.5}, and negative temperature. GOM concentrations were positively correlated with PBM
445 concentrations, which implies that these two species probably originated from the same sources. The
446 high positive loadings of PBM, GOM, and some particle pollutants may indicate that the main source of
447 PBM and GOM is local emissions. The long-distance transport of particle pollutants from the Indian
448 subcontinent may have heavy wet deposition when the air mass climbs into the Tibetan Plateau and
449 cannot reach Nyingchi successfully. Thus, the local monitored particle pollutants, as well as easy-
450 deposition pollutants, may mainly originate from regional emissions. One possible source is from yak
451 dung; in the Tibetan Plateau, yak dung is a widely used household biofuel (Xiao et al., 2015) and the
452 burning of yak dung may release Hg and other particulate matter.

453 Meteorology factor (F3) was found during the ISM period with positive temperature, wind speed,
454 solar radiation, and negative humidity and rain, which are likely associated with meteorological
455 conditions. This factor shows that meteorological conditions may profoundly affect the overall local
456 pollutant distributions during the ISM period, which suggests that the air mass carried by the ISM not
457 only cannot increase the long-distance transportation of pollutants to the Nyingchi area, but may also
458 reduce the local contribution of pollution. For existing pollutants, the strong positive loading of solar
459 radiation may indicate that pollutant reactions under strong radiation are relatively active in this high-
460 altitude region. The strong negative humidity and rain may indicate that rain has played a strong role in
461 the cleaning process, especially during the ISM1 and ISM2 periods, when precipitation is relatively
462 strong.

463 Factor 4 had a strong positive correlation with GEM, ROM, and solar radiation, and negative loading
464 with humidity during the ISM1 period. This suggests that as solar radiation increases in the afternoon
465 (Figure 3), more GEM and GOM are emitted to the air, which may reflect the snow/ice melt process
466 (Huang et al., 2010; Dommergue et al., 2003). Previous studies have shown that the snowmelt process
467 can increase atmospheric GEM concentration (Huang et al., 2010; Dommergue et al., 2003). GEM may
468 come from the evaporation of snow melting or be driven by the photoreduction of snow Hg^{II} (Song et al.,
469 2018). Previous simulations indicated that the oxidation of GEM may occur at the snow/ice interface in
470 the action of solar radiation, leading to extra GOM release in the ISM1 period. The peak concentrations
471 of GEM and GOM both appeared in the afternoon during the ISM1 period, when the solar radiation was
472 the highest and humidity was the lowest. The increase in GEM and GOM concentrations may be related
473 to solar radiation, according to the PCA results.

474 3.5 Implications

475 The Tibetan Plateau is a direct invasion target of the ISM. Blocked by the high altitude of the
476 Himalayas, the Indian monsoon could bypass the high mountains and enter Tibet via the YZB Grand
477 Canyon. When the summer monsoon enters Tibet, it is generally believed that pollutants from India and
478 the Indian Ocean, as well as large amounts of water vapor, may be carried along with the air masses (Lin

479 et al., 2019; Yang et al., 2013; Wang et al., 2018). Located in the water vapor channel where the Indian
480 monsoon enters, Nyingchi is believed to receive a large amount of foreign air mass (Yang et al., 2013).
481 Considering that Nyingchi has little local emission because of the sparse population and lack of industry,
482 the pollutants present in the area should mostly have been transported by monsoons over long distances.
483 However, our monitoring results show that during the ISM period, the Hg concentrations in the Nyingchi
484 are extremely low ($0.95 \pm 0.27 \text{ ng m}^{-3}$); lower than the background Hg concentration in the Northern
485 Hemisphere and the Hg concentrations observed at surrounding monitoring sites in the literature (Table
486 1).

487 The low concentration during the ISM period may be related to the regional deposition process and
488 complex regional terrain. When monsoon winds carry large amounts of Indian Ocean moisture and enter
489 the YZB Grand Canyon, strong wet deposition occurs during transport due to an increase in elevation
490 and a decrease in temperature. The process of rainwater scouring from wet deposition may result in
491 significant deposition of pollutants from carried air masses (Lindberg and Stratton, 1998; Seigneur et al.,
492 2006). Meanwhile, the air flow in the canyon is slow owing to the complex terrain. The slow migration
493 of the air mass further strengthens the deposition process. In addition, during the ISM period, the dense
494 forest in the canyon may deplete some of the mercury during transport (Fu et al., 2016). Therefore,
495 pollutants from the Indian subcontinent struggle to go deep into the Tibetan Plateau during the ISM
496 period. The deposited pollutants may flow into the downstream area via rivers to Southeast Asia and
497 South Asia, and these transportation mechanisms needs to be further studied. However, long-distance
498 transboundary transport remains an important mechanism of Hg distribution in this area during the period
499 of westerly circulation. As discussed in Section 3.1, the Hg concentration in Nyingchi during PISM
500 period ($1.20 \pm 0.35 \text{ ng m}^{-3}$) was much higher than that during the ISM period ($0.95 \pm 0.27 \text{ ng m}^{-3}$). The high
501 Hg concentration during the PISM period may indicate that a large amount of external source Hg entered
502 the Nyingchi area during the non-ISM period, which needs to be further studied.

503 The results of our previous study on Qomolangma were different from those in Nyingchi. At
504 Qomolangma (Lin et al., 2019), the ISM was the main period of transboundary transport of Hg, and the
505 PISM period accounted for a smaller amount of transport. The difference in Hg transportation patterns
506 between the two sites may mainly originate from the difference in the geographical location, with
507 different actions of the westerly circulation and the Indian summer wind. Qomolangma is located on the
508 northern side of the Himalayas, a typical terrain on the southern side of the Tibetan Plateau. The Nyingchi
509 area is another typical pathway for air masses to enter the Tibetan Plateau. Together, they describe two
510 typical transboundary transport patterns of Hg occurring on the Tibetan Plateau at different periods of
511 the year.

512 4. Conclusions

513 Comprehensive species Hg monitoring was carried out in Nyingchi, a high-altitude site in the
514 southeast of the Tibetan Plateau. Nyingchi is located on the main pathway for water vapor carried by the
515 monsoon to enter Tibet during the ISM period, which could characterize the spread of pollutants from
516 the Indian subcontinent. The atmospheric Hg concentrations during the PISM period ($1.20 \pm 0.35 \text{ ng m}^{-3}$,
517 $13.5 \pm 7.3 \text{ pg m}^{-3}$, and $11.4 \pm 4.8 \text{ pg m}^{-3}$, for GEM, GOM, and PBM respectively) were relatively higher
518 than those during the ISM period ($0.95 \pm 0.21 \text{ ng m}^{-3}$, $12.7 \pm 14.3 \text{ pg m}^{-3}$, and $8.8 \pm 6.0 \text{ pg m}^{-3}$, for GEM,

519 GOM, and PBM respectively). The Hg concentration in Nyingchi is particularly low compared with other
520 high-altitude stations around the world. GEM concentration shows a distinct and unique diurnal variation,
521 with a gradual increase in GEM concentration during the day and a maximum concentration at night.
522 This diurnal variation may be due to the re-emission of GEM by snowmelt and the trapping effect of
523 pollutants by the planetary boundary layer at night.

524 According to the trajectory model, atmospheric Hg in the Nyingchi area originated mainly from or
525 passed through Nepal and central Tibet during the PISM period. During the ISM period, Hg may mainly
526 originate from northeast India and the Bay of Bengal. During the ISM period, the Hg concentrations were
527 particularly low because of the strong deposition process during transportation. Through comprehensive
528 PCA analysis using local meteorological conditions and multiple pollutants, long-distance transport, local
529 emissions, meteorological factor, and snowmelt factor have been identified to affect local Hg
530 concentrations. In the Nyingchi area, Hg mainly comes from westerly circulation during the non-ISM
531 period. During the ISM period, pollutants from the Indian subcontinent may travel to South Asia and
532 Southeast Asia along the major rivers in this area.

552 Figure 1. Location of the South-East Tibetan Plateau Station for Integrated Observation and
553 Research of Alpine Environment (SET station or Nyingchi station, the red star). SET station is
554 located in a water vapor channel from the Ganges River Plain to the Tibetan Plateau. The red dot is
555 Lhasa, the capital city of the Tibet Autonomous Region, which is the most densely populated city in
556 Tibet; the other red dot is the nearest town to the monitoring site, Bayi Town.

557 Figure 2. Time serious of GEM, GOM, and PBM concentrations and the daily rainfall over the

558 sampling period. The GEM concentration resolution is 5 min, and the GOM, PBM, and rain
559 resolutions are 2 hours. According to the characters of monsoon development and precipitation, the
560 monitoring periods are divided into four segments, namely PISM (before May), ISM1 (1 May- 2
561 June), ISM2 (3 June – 8 August), and ISM3 (after 9 August).

562 Figure 3. GEM concentrations obtained through passive samplers throughout the year. The black
563 squares represent the atmospheric Hg concentrations obtained by passive sampling, and the upper
564 and lower error lines are the standard errors of the passive samples monitored during the same time
565 period. The red dots represent the GEM concentrations obtained through the Tekran instrument. The
566 green horizontal line indicates the average of the atmospheric mercury concentrations during this
567 period.

568 Figure 4. Diurnal variation of species Hg, concentrations of some other pollutants and
569 meteorological information from PISM to ISM1-3 periods. The short horizontal line represents the
570 concentration error range for each time period.

571 Figure 5. Clusters of the back trajectory analysis from SET site during PISM to ISM3 periods. The
572 thickness of the line represents the ratio of the cluster in the time period, and the color of the line
573 represents the GEM concentration carried by the cluster, the background is the globally Hg emission
574 inventory developed by UNEP(UNEP, 2013a).

834 Quantifying sources, transport, deposition, and radiative forcing of black carbon over the
835 Himalayas and Tibetan Plateau, *Atmospheric Chemistry and Physics*, 15, 6205-6223, 2015b.
836 Zhang, R., Wang, Y., He, Q., Chen, L., Zhang, Y., Qu, H., Smeltzer, C., Li, J., Alvarado, L., Vrekoussis,
837 M. J. A. C., and Physics: Enhanced trans-Himalaya pollution transport to the Tibetan Plateau by
838 cut-off low systems, 17, 2017.
839 Zhang, W., Tong, Y., Hu, D., Ou, L., and Wang, X.: Characterization of atmospheric mercury
840 concentrations along an urban-rural gradient using a newly developed passive sampler,
841 *Atmospheric Environment*, 47, 26-32, 10.1016/j.atmosenv.2011.11.046, 2012.
842 Zhou, H., Hopke, P. K., Zhou, C., and Holsen, T. M. J. S. o. t. T. E.: Ambient mercury source
843 identification at a New York State urban site: Rochester, NY, 650, 1327-1337, 2019.
844 Zhu, J., Xia, X., Che, H., Wang, J., Cong, Z., Zhao, T., Kang, S., Zhang, X., Yu, X., Zhang, Y. J. A. C.,
845 and Physics: Spatiotemporal variation of aerosol and potential long-range transport impact over
846 the Tibetan Plateau, China, 19, 14637-14656, 2019.
847
